Mobile identity management is in its infancy. GSM networks, for example, provide management of SIM identities as a kind of mobile identity management, but they do not meet all the requirements for a complete Mobile identity management. Unlike static identity, already implemented in

Web 2.0 identity, dynamic aspects, such as the user's position or the temporal context, gain increasingly importance for new kinds of mobile applications [44].

Mobile identity (MId) infrastructure solutions have evolved over time and can be classified into three solutions. The first proposed solution is just an extension of wired identity management to mobile Internet. This is the widespread solution, which is limited to the users of mobile devices running the same operating system as wired solution. This limitation is expected to evolve over time mainly with the large deployment of Web services. Some specifications, such as Liberty Alliance specifications, have been developed for identity management including mobility. However, several limitations are observed when the MId system is derived from fixed context. These limitations are principally due to the assumptions during their design and they do not match well with extra requirement of mobility [1].

Many improvements such as interoperability, privacy and security are to be operated. Also, older centralized PKI must be replaced by a modern trust management system or at least a decentralized PKI.

The second solution is capable of providing an alternative to the prevalent Internet derived MId infrastructure. This consists of either connected (Cellular phones) or unconnected (Smartcards) mobiles devices.

The third one consists of using implantable radio frequency identity (RFID) devices. This approach is expected to increase rapidly even if the market penetration is smaller than cellular phones.

In addition, the sensitivity risk of data related to different applications and services are seldom at the same level and the number of identifiers used by a person is in constant increasing. Thus, there is a real need of different kind of credentials associated with different kind of applications. Indeed, a tool at the user side capable of managing the credentials and identifies is inevitable. With the increasing capacity of CPU power and the spreading number of mobile phone with a SIM card, mobile phones can be considered as a Personal Authentication Device (PDA). They can hold securely the users' credentials, password and even identities. Thereby, we introduced a new efficient Identity management device at the user side able to facilitate the memorization in one hand, and strengthen the security by limiting the number of passwords and their weakness in other hand. All wired identity management can be deployed using PDA. In addition, many different authentication architectures become possible and easy to implement such as dual channel authentication.

PDA as Solution to Strong Authentication

PDA is a tamper-resistant hardware device which could include smart card and sensors or not. As it is used for authentication it is called a personal authentication device (PDA) [45]. This term has been early used in the context of security by Wong and al. [46]. The approach is the same and the only thing change so far is the performance of the mobile device has radically changed. This is the opportunity to emphasis the user centricity as the PDA could strengthen the user experience and to facilitate the automation and system support of the identity management at the user side. The Figure 25.22 illustrated the combination of PDA and silo model. The user stores his/her identity in the PDA. Whenever he/she would like to connect to a Service provider.

1. He/she authenticates her/himself with a PIN code to use the PDA.
2. The user choose the Password to be used for his/her connection to the specific service provider.
3. The user launch and log to the specific service provider by entering his/her Username and the Password.

The PDA is a good device to tackle the weakness and non-convenience of password authentication. Thereby, we have a user friendly and user centric application and even introducing stronger authentication. The fundamental advantage of PDA comparing with common PC using common operating systems such as windows or linux is that PDA has a robust isolation of processes. Therefore, compromising one application does not compromise all the applications. This advantage is becoming less important for mobile phone as flexibility is introduced by manufacturers a lot of vulnerabilities is also introduced. We have seen many viruses for mobile phones and even nowadays we have viruses for RFID. This vulnerability can compromise authentication and even biometrics authentication. That's why we should be very vigilant in implementing security in

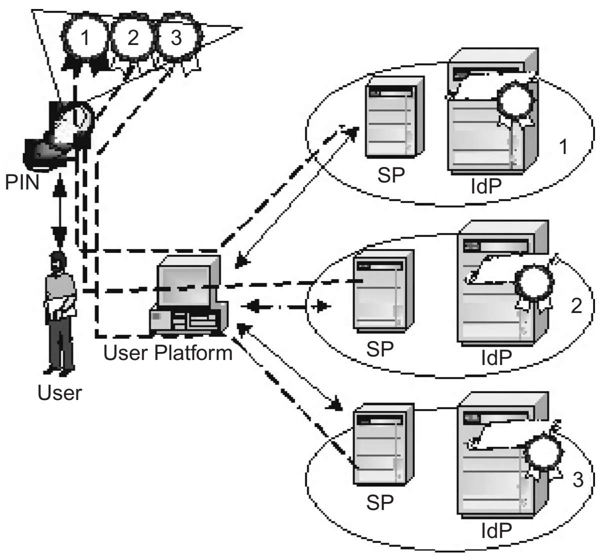

FIGURE 25.22 Integration of PDA in silo model.

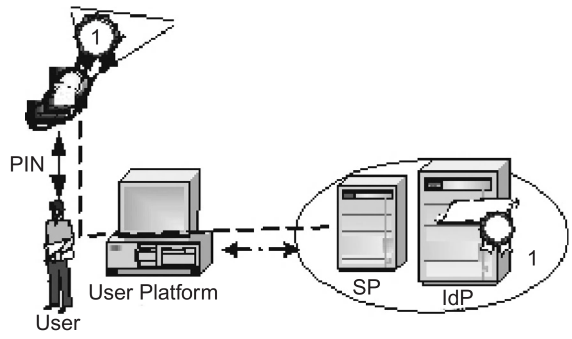

FIGURE 25.23 Single channel authentication.

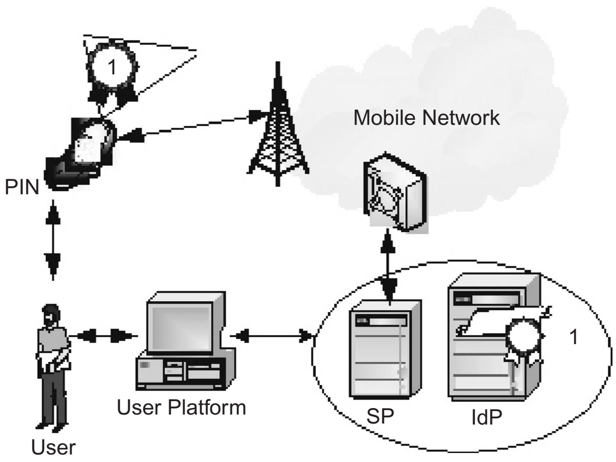

FIGURE 25.24 Dual channel authentication.

PDA devices. An ideal device is the USB stick running a standalone OS, and integrating a biometric reader and mobile network access. A can find some of them with fingerprint reader for a reasonable price.

Two main categories can group many authentication architectures that could be implemented in a PDA. There are single and dual channel authentications. Thereby, the cost, the risk and the non-convenience could be tackled at the same time.

Figure 25.23 illustrates the principle of single channel authentication, which is the first application of the PDA. Figure 25.24 illustrates the second principle of dual-channel authentication, which is more secure.

Different Kinds of Strong Authentication Through a Mobile PDA

The mobile network mainly GSM can help to overcome a lot of security vulnerabilities such as phishing or man-in-the-middle. It attracts all business that would like to deploy double channel authentication but are worry about cost and usability. The near-ubiquity of the mobile

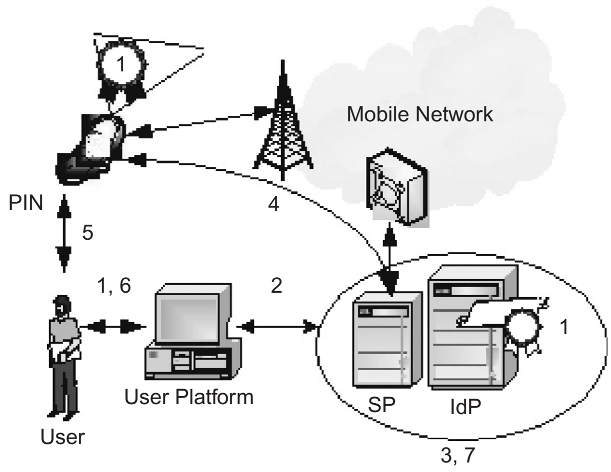

FIGURE 25.25 Scenario of SMS double channel authentication.

network has made feasible the utilization of this approach and even being adopted by some banks.

SMS Based One-Time Password (OTP)

The main advantages in mobile network are the facility and usability to send and receive SMSs. Moreover, they could be used to setup and download easily Java program to the mobile device. In addition, mobile devices are using smart card that can securely calculate and store claims.

The cost is minimized by adopting a mobile device using SMS to receive OTP instead of a special hardware that can generate OTP. The scenario implemented by some banks is illustrated in Figure 25.25. First of all, the user switches his/her mobile phone and enters his PIN code then:

1. The user log into his online account by entering his/her Username and Password (U/P)
2. The Web site received the couple U/P
3. The server verifies the couple
4. Send a SMS message with OTP
5. The user reads the message
6. The user enters the OPT into online account
7. The server verify the OPT and give access

The problem of this approach is the fact that the cost is assumed by the service provider. In addition, some drawbacks are very common mainly in some developing countries such as lack of coverage and SMS latency. Of course, the attack of the man-in-the-middle is not overcome by this approach.

Soft Token Application

In this case, the PDA is used as a token emitter. The application is previously downloaded. SMS could be sent

to the user in order to set up the application that will play the role of soft token.

The scenario is exactly identical to the SMS but only the user generates his/her OTP using the soft token instead of waiting for a SMS message. The cost is less than the SMS based OTP. This approach is a single channel authentication that is not dependent on mobile network coverage neither on his latency. Furthermore, the attack of the man-in-the-middle is not tackle.

Full Option Mobile Solution

We have seen in the two previously scenarios that the attacks of the man-in-the-middle is not addressed. It exist a counterattack to this security issue consisting of using the second channel to completely control all the transactions over the online connection. Of course, the security of this approach is based on the assumption that it is difficult for an attacker to steal the user's personal mobile phone or to attack the mobile network. Anyway, we have developed an application to crypt the SMS message which minimizes the risk of attacks. The scenario is illustrated in the Figure 25.26 and it is as follows:

1. The user login on online account using token
2. The server receives the token
3. The server verifies the token
4. the access is given to the service
5. the user request a transaction
6. SMS message is send with the requested transaction and a confirmation code
7. The user verifies the transaction
8. He enters the confirmation code
9. The server verifies and execute the transaction
10. The server sends a transaction confirmation

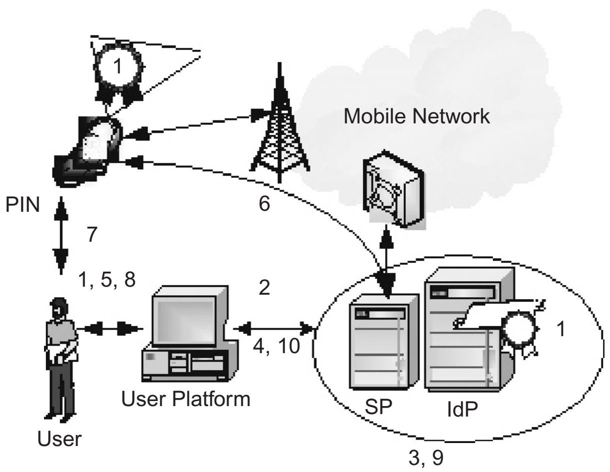

FIGURE 25.26 Secure transaction via SMS.

Future of Mobile User-Centric Identity Management in an Ambient Intelligence (AmI) World

AmI manifests itself through a collection of everyday devices incorporating computing and networking capabilities that enable them to interact with each other, make intelligent decisions and interact with users through user friendly multimodal interfaces. Ambient intelligence is driven by users' needs and the design of its capabilities should be driven by users' requirements.

Ambient Intelligence technologies are expected to combine concepts of ubiquitous computing and intelligent systems putting humans in the center of technological developments. Indeed, the Internet extension to home and mobile networks, the multiplication of modes of connection will make the individual the central point. Therefore, the identity is a challenge in this environment and will guarantee the infatuation with Ambient Intelligence. Moreover, AmI will be the future environment where we shall be surrounded by mobile devices which will be more and more used for mobile interactions with things, places and people.

The low-cost and the shrinking size of sensors as well as the ease of deployment will aid ambient intelligence research efforts for rapid prototyping. Evidently, a sensor combined with unique biometric identifiers is becoming more frequently utilized in access a system, and supposedly provide proof of a person's identity and thus accountability for subsequent actions. To explore these new AmI technologies, it is easier to investigate a scenario related to ubiquitous computing in an ambient intelligence environment.

AmI Scenario

A person having a mobile device, GPS (or equivalent) and an ad-hoc communication network connected to sensors, visits an intelligent environment supermarket and would like to acquire some merchandise. We illustrate below how this person can benefit from mobile identity.

When this person enters the supermarket, he/she is identified by means of his/her mobile device or implemented RFID tag and a special menu is displayed to him/her. His/her profile, related to his/her context identity, announces a discount if there is one.

The members of his/her social network could propose him/her a connection if they are present and even guide him to their location. Merchandise on display could communicate with his/her device to show prices and details. Location-based services could be offered to quickly find his/her specific articles.

His device could help him to find diabetic foods or any restrictions associated with specific articles. A secure Web connection could be initiated to give more information about purchases and the user account.

An adaptive screen could be used by the supermarket to show him/her information that is too extensive for his/her device screen. Payment could be carried out using payment identity stored in his/her device and even a biometric identity to prevent identity theft.

Identity information and profiling should be portable and seamless for interoperability. The identity must be managed to ensure user control. Power and performance management in this environment is a must. The concept of authentication between electronic devices is also highlighted.

In order to use identity management, the user needs an appropriate tool to facilitate the management for the disclosure of personal data. A usable and secure tool should be proposed to help even inexperienced users manage their general security needs when using the network.

We need mobile identity management, which is a concept that allows the user to keep his or her privacy, depending on the situation. By using identity management, the user's device acts in a similar way to the user. In different contexts, the user presents a different appearance. Devices controlled by identity management change their behavior similar to the way in which a user would.

Requirements for Mobile User-centric Identity Management in an AmI world

As the network evolution is toward mobility with the proliferation of ubiquitous and pervasive computing systems, the importance of identity management to build trust relationships in the context of electronic and mobile (e/m) government and business is evident [47,48]. Thereby, all these systems require advanced, automated identity management systems in order to be cost effective and easy to use.

Several mobile devices such as mobile phones, smart cards of RFID are used for mobility. As mobile devices have fixed identifiers, they are essentially providing a mobile identity that can be liked to a user. Mobile identity takes into account location data of mobile users in addition to their personal data. A recent court decision in the UK has established as proof of location of the accused the location trace of his mobile phone which implies a de facto recognition of the identity of a citizen as the identity of her mobile telephones [1].

That is why Mobile identity management (MIdm) is necessary to empower mobile users to manage their mobile identities to enforce their security and privacy interests. Mobile identity management is a special kind of identity management. For this purpose, mobile users must be able to control the disclosure of their mobile identity dependent on the respective service provider and also their location via mobile identity management systems.

Ambient Intelligence emphasizes the principles of secure communication anywhere, anytime, with anything. The evolution of AmI will directly influence identity management with this requirement to ensure mutual interaction between users and things. *Being Anywhere* will imply more and more mobility, interoperability and profiling. *At Anytime* will imply online as well as offline connection as the network does not have a 100% coverage and will imply power as well as performance management in order to optimize use battery. *With anything* will imply sensor use, biometrics and RFID interaction; and *Securely* implies more and more integration of privacy, authentication, anonymity and prevention of identity theft.

From multilateral security [49,50], Jendricke [31] has derived privacy principles for MIdm and we have completed them below with a few other important principles. Management systems are as follows:

1. Context-detection
   a. Sensors
   b. Biometrics
   c. RFID
2. Anonymity
3. Security
   a. Confidentiality
   b. Integrity
   c. Non-repudiation
   d. Availability
4. Privacy
   a. Protection of location information
5. Trustworthiness
   a. Segregation of power, separating knowledge, integrating independent parties
   b. Using Open Source
   c. Trusted seals of approval seal
6. Law Enforcement / Liability
   a. Digital evidence
   b. Digital signatures
   c. Data retention
7. Usability
   a. Comfortable and informative user interfaces
   b. Training and education
   c. Reduction of system' complexity
   d. Raising awareness
8. Affordability
   a. Power of market :Produce MIMS that are competitive and are able to reach a remarkable penetration of market
   b. Using open source building blocks
   c. Subsidies for development, use, operation, etc.
9. Power management: the energy provided by the batteries of mobile devices is limited and that energy must be used with care on energy-friendly applications and services
10. Online and offline identity proof
11. Small screen size and lower computational capability

12. Interoperability
   a. Identity needs to be portable to be understood by any device.

7. SUMMARY

The Internet is being used more and more; but, the fact that the Internet has not been developed with an adequate identity layer is a major security risk. Password fatigue and online fraud are a growing problem and are damaging user confidence. However it is a difficult problem to solve both from a technical point of view and a business model point of view. Users are not prepared to pay themselves for identity management and expect the service provider should provide it to them. It is the reason that a number of major initiatives trying to provide a more adequate identity layer for the Internet surveyed above and already present in the first version of this chapter have been discontinued due to a failing business model, for example, Sxip. If the user experience is too long or require retyping personal information, many users may not take the time to join the new service. "Social login" provided by online social networks has emerged as the main identity management solution adopted by the users to log in to new Web sites and services because they did not have to type their personal information again. It has been to the detriment to the privacy of the users but it is clear that it does not worry the users because they are not able to take into account the effect of this privacy leak in the long term. They prefer accessing the service they want to use, such as Facebook, even if it may impact their privacy in the long term. Thus, although "social login" do not fulfill all identity management requirements that have been presented in this chapter since its first version, "social login" has won over many other identity management initiatives, even if a few of them are still used underneath, e.g., OpenId. User management providers listed in Section 4 and aggregating several "social login" solutions for Web sites and services are promising. Another development concerns mobile identity management and those new user management providers may also play an importation role in this respect.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? A digital identity is a representation of an entity in a general context.

2. True or False? Identity management refers to "the process of representing, using, maintaining, deprovisioning and authenticating entities as digital identities in computer networks."

3. True or False? Privacy is a central issue, due to the fact that the official authorities of almost all countries have legal strict policies related to identity.

4. True or False? The evolution of the identity management system is away from the simplification of user experience and reinforcing authentication.

5. True or False? The security is also compromised with the proliferation of the user's password and even by it's strength.

Multiple Choice

1. The main identity management system deployed currently in the world of the Internet is known as the?
   A. Federated identity management model
   B. Identity life cycle
   C. Aggregate identity
   D. Executive management model
   E. Silo model

2. ________________ in centralized identity infrastructures, can't solve the problem of cross-organizational authentication and authorization?
   A. Centrally managed repositories
   B. Information system auditors
   C. IT personnel
   D. Systems Administrators
   E. All of the above

3. A relatively simple ____________ model is to build a platform that centralizes identities?
   A. Common user identity management
   B. Simple centralized identity management
   C. Unique identity management
   D. Meta directory
   E. Executive Management

4. What provides an abstraction boundary between application and the actual implementation?
   A. Single point of administration
   B. Redundant directory information
   C. Single point of reference
   D. Business impact analysis
   E. All of the above

5. What directories are not located in the same physical structure as the Web home directory, but look as if they were to Web clients?
   A. Single Sign-On
   B. Seamless
   C. Session
   D. Virtual
   E. Flexible

EXERCISE

Problem

What is a digital identity?

Intrusion Prevention and Detection Systems

Christopher Day
Terremark Worldwide, Inc.

1. WHAT IS AN 'INTRUSION' ANYWAY?

Information security concerns itself with the confidentiality, integrity and availability of information systems and the information or data they contain and process. An 'intrusion' then is any action taken by an adversary that has a negative impact on the confidentiality, integrity, or availability of that information. Given such a broad definition of 'intrusion' it is instructive to examine a number of commonly occurring classes of information system (IS) intrusions.

2. PHYSICAL THEFT

Having physical access to a computer system allows an adversary to bypass most security protections put in place to prevent unauthorized access. By stealing a computer system, the adversary has all the physical access he or she could want and unless the sensitive data on the system is strongly encrypted (see sidebar, "Definition of Encryption"), the data is very likely to be compromised. This issue is most prevalent with laptop loss and theft. Given the processing and storage capacity of even low-cost laptops today, a great deal of sensitive information can be put at risk if a laptop containing this data is stolen. In May of 2006, it was revealed that over 26 million military veterans' personal information including names, social security numbers, addresses, and some disability data was on a Veteran Affairs staffer's laptop that was stolen from his home [2a]. The stolen data was of the type that is often used to commit identity theft and due to the large number of impacted veterans, there was a great deal of concern about this theft and the lack of security around such a sensitive collection of data. In another example, in May of 2012 it was revealed that an unencrypted laptop containing medical records for 2,159 patients was stolen Boston Children's Hospital staffer while travelling overseas for a conference [2b].

Definition of Encryption

Encryption is the process of protecting the content or meaning of a message or other kinds of data [3]. Modern encryption algorithms are based on complex mathematical functions that scramble the original, clear-text message or data in such a way that makes it difficult or impossible for an adversary to read or access the data without the proper key to reverse the scrambling. The encryption key is typically a large number of values that when fed into the encryption algorithm scrambles and unscrambles the data being protected and without which it is extremely difficult or impossible to decrypt encrypted data. The science of encryption is called cryptography and is a broad and technical subject.

3. ABUSE OF PRIVILEGES (THE INSIDER THREAT)

An insider is an individual who, due to their role in the organization, has some level of authorized access to the IS environment and systems. The level of access can range from that of a regular user to a system administrator with nearly unlimited privileges. When an insider abuses their privileges the impact can be devastating. Even a relatively limited-privilege user is already starting with an advantage over an outsider due to their knowledge of the IS environment, critical business processes, and potential knowledge of security weaknesses or 'soft spots'. An insider may use their access to steal sensitive data such as customer databases, trade secrets, national security secrets, or personally identifiable information (PII) (see sidebar, "Definition of Personally Identifiable Information"). Because they are a trusted user and given that many intrusion detection systems are designed to monitor for attacks from outsiders, an insider's privileged abuse can go on for a long time unnoticed thus compounding the damage. In 2010, US soldier Bradley Manning allegedly utilized his legitimate access to the

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00026-X

Secret Internet Protocol Router Network (SIPRNet) to pass classified information to the whistleblower website WikiLeaks in what has been described as the largest known theft of classified information in US history [4]. An appropriately privileged user may also use their access to make unauthorized modifications to systems that can undermine the security of the environment. These changes can range from creating "backdoor" accounts used to preserve access in the event of termination to installing so-called "logic bombs" which are programs designed to cause damage to systems or data at some predetermined point in time, often as a form of retribution for some real or perceived sleight.

Definition of Personally Identifiable Information

Personally Identifiable Information (PII) is a set of information such as name, address, social security number, financial account number, credit card number, and driver's license number. This class of information is considered particularly sensitive due to its value to identify thieves and others who commit financial crimes such as credit card fraud. Most states in the United States have some form of data breach disclosure law which imposes a burden of notification on any organization which suffers unauthorized access, loss, or theft of unencrypted PII. It is worth noting that all of the current laws provide a level of 'Safe Harbor' for organizations that suffer a PII loss if the PII was encrypted. California's SB1386 was the first and arguably most well known of the disclosure laws.

4. UNAUTHORIZED ACCESS BY OUTSIDER

An outsider is considered anyone who does not have authorized access privileges to an information system or environment. To gain access the outsider may try to gain possession of valid system credentials via social engineering or even by guessing username and password pairs in a brute force attack. Alternatively, the outsider may attempt to exploit a vulnerability in the target system to gain access. Often the result of successfully exploiting a system vulnerability leads to some form of high-privileged access to the target, such as an "Administrator" or Administrator-equivalent account on a Microsoft Windows system or "root" or root-equivalent account on a UNIX or Linux-based system. Once an outsider has this level of access on a system he or she effectively "owns" that system and can steal data or use the system as a launching point to attack other systems.

5. MALWARE INFECTION

Malware can be generally defined as "a set of instructions that run on your computer and make your system do something that allow an attacker to make it do what he wants it to do" [5]. Historically, malware (see sidebar, "Classifying Malware") in the form of viruses and worms was more of a disruptive nuisance than a real threat but it has been evolving as the weapon of choice for many attackers due to the increased sophistication, stealthiness, and scalability of intrusion-focused malware. Today, we see malware being used by intruders to gain access to systems, search for valuable data such as PII and passwords, monitor real-time communications, provide remote access/control, and automatically attack other systems just to name a few capabilities. Using malware as an attack method also provides the attacker with a "stand-off" capability that reduces the risk of identification, pursuit, and prosecution. By "stand-off" we mean the ability to launch the malware via a number of anonymous methods such as an insecure, open public wireless access point and once the malware has gained access to the intended target or targets, manage the malware via a distributed command and control system such as Internet Relay Chat (IRC), web site pages, dynamic DNS, as well as completely novel mechanisms. Not only does the command and control network help mask the location and identity of the attacker but it also provides a scalable way to manage many compromised systems at once, maximizing the results for the attacker. In some cases the number of controlled machines can be astronomical, such as with the Storm worm infection which, depending on the estimate, ranged somewhere between one and ten million compromised systems [6]. These large collections of compromised systems are often referred to as "bot-nets".

Classifying Malware

Malware takes many forms but can be roughly classified by function and replication method.

- *Virus*: Self-replicating code that attaches itself to another program. It typically relies on human interaction to start the host program and activate the virus. A virus usually has a limited function set and its creator has no further interaction with it once released. Examples are Melissa, Michelangelo, and Sobig.
- *Worm*: Self-replicating code that propagates over a network, usually without human interaction. Most worms take advantage of a known vulnerability in systems and compromise those that aren't properly patched. Worm creators have begun experimenting with updateable code and payloads, such as seen with the Storm worm [5]. Examples are Code Red, SQL Slammer, and Blaster.
- *Backdoor*: A program that bypasses standard security controls to provide an attacker access, often in a stealthy way. Backdoors rarely have self-replicating capability and are either installed manually by an attacker after compromising a system to facilitate future access or by other self-propagating malware as payload. Examples are Back Orifice, Tini, and netcat (netcat has legitimate uses as well).

- *Trojan Horse*: A program that masquerades as a legitimate, useful program while also performing malicious functions in the background. Trojans are often used to steal data or monitor user actions and can provide a backdoor function as well. Examples of two well-known programs that have had Trojaned versions circulated on the Internet are tcpdump and Kazaa.
- *User-level Rootkit*: Trojan/ backdoor code that modifies operating system software so the attacker can maintain privileged access on a machine but remain hidden. For example, the rootkit will remove malicious processes from user-requested process lists. This form of rootkit is called user-level because it manipulates operating system components utilized by users. This form of rootkit can often be uncovered by the use of trusted tools and software since the core of the operating system is still unaffected. Examples of user-level rootkits are the Linux Rootkit (LRK) family and FakeGINA.
- *Kernel-level Rootkit*: Trojan/ backdoor code that modifies the core or kernel of the operating system to provide the intruder the highest level of access and stealth. A kernel-level rootkit inserts itself into the core of the operating system, the kernel, and intercepts system calls and thus can remain hidden even from trusted tools brought onto the system from the outside by an investigator. Effectively, nothing the compromised system tells a user can be trusted and detecting and removing kernel-level rootkits is very difficult and often requires advanced technologies and techniques. Examples are Adore and Hacker Defender.
- *Blended Malware*: More recent forms of malware combine features and capabilities discussed above into one program. For example, one might see a Trojan Horse that once activated by the user inserts a backdoor utilizing user-level rootkit capabilities to stay hidden and provide a remote handler with access. Examples of blended malware are Lion and Bugbear.

6. THE ROLE OF THE '0-DAY'

The Holy Grail for vulnerability researchers and exploit writers is to discover a previously unknown and exploitable vulnerability, often referred to as a 0-day exploit (pronounced 'zero day' or 'oh day'). Given that others have not discovered the vulnerability, all systems running the vulnerable code will be unpatched and possible targets for attack and compromise. The danger of a given 0-day is a function of how widespread the vulnerable software is and what level of access it gives the attacker. For example, a reliable 0-day for something as widespread as the ubiquitous Apache Web server that somehow yields root or Administrator-level access to the attacker is far more dangerous and valuable than an exploit that works against an obscure point-of-sale system used by only a few hundred users (unless the attacker's target is that very set of users).

In addition to potentially having a large, vulnerable target set to exploit, the owner of a 0-day also has the advantage that most intrusion detection and prevention systems will not trigger on the exploit for the very fact that it has never been seen before and the various IDS/ IPS technologies will not have signature patterns for the exploit yet. We will discuss this issue in more detail later.

It is this combination of many unpatched targets and the ability to potentially evade many forms of intrusion detection and prevention systems that make 0-days such a powerful weapon in the hands of an attacker. Many legitimate security and vulnerability researchers explore software systems to uncover 0-days and report them to the appropriate software vendor in the hopes of preventing malicious individuals from finding and using them first. Those who intend to use 0-days for illicit purposes guard the knowledge of a 0-day very carefully lest it become widely and publically known and effective countermeasures, including vendor software patches, can be deployed.

One of the more disturbing issues regarding 0-days is their lifetimes. The lifetime of a 0-day is the amount of time between the discovery of the vulnerability and public disclosure through vendor or researcher announcement, mailing lists, and so on. By the very nature of 0-day discovery and disclosure it is difficult to get reliable statistics on lifetimes but one vulnerability research organization claims their studies indicate an average 0-day lifetime of 348 days [7]. Hence, if malicious attackers have a high-value 0-day in hand, they may have almost a year to put it to most effective use. If used in a stealthy manner so as not to tip off system defenders, vendors, and researchers this sort of 0-day can yield many high-value compromised systems for the attackers. While there has been no official substantiation, there has been a great deal of speculation that the "Titan Rain" series of attacks against sensitive United States government networks between 2003 and 2005 utilized a set of 0-days against Microsoft software [8,9].

7. THE ROGUE'S GALLERY: ATTACKERS AND MOTIVES

Now that we have examined some of the more common forms computer system intrusions take, it is worthwhile to discuss those who are behind these attacks and attempt to understand their motivations. The appropriate selection of intrusion detection and prevention technologies is dependent on the threat being defended against, the class of adversary and the value of the asset being protected.

While it is always risky to generalize, those who attack computer systems for illicit purposes can be placed into a number of broad categories. At minimum this gives us a "capability spectrum" of attackers to begin to understand motivations and, therefore, threats.

Script Kiddy

The pejorative term "script kiddy" is used to describe those who have little or no skill at writing or understanding how vulnerabilities are discovered and exploits written but download and utilize other's exploits available on the Internet to attack vulnerable systems. Typically, script kiddies are not a threat to a well managed, patched environment as they are usually relegated to using publically known and available exploits for which patches and detection signatures already exist.

Joy Rider

This type of attacker is often represented by those with potentially significant skills in discovering vulnerabilities and writing exploits but who rarely have any real malicious intent when they access systems they are not authorized on. In a sense they are "exploring" for the pleasure of it. However, while their intentions are not directly malicious, their actions can represent a major source of distraction and cost to system administrators who must respond to the intrusion especially if the compromised system contained sensitive data such as PII where a public disclosure may be required.

Mercenary

Since the late nineties there has been a growing market for those who possess the skills to compromise computer systems and are willing to sell them and those willing to purchase these skills [10]. Organized crime is a large consumer of these services and computer crime has seen a significant increase in both frequency and severity over the last decade, primarily driven by direct, illicit financial gain and identity theft [11]. In fact, so successful have these groups become that a full-blown market has emerged including support organizations offering technical support for rented bot-nets and online trading environments for the exchange of stolen credit card data and PII. Stolen data has a tangible financial value as can be seen by Table 26.1, which indicates the dollar value ranges for various types of PII.

TABLE 26.1 PII Values.

Goods and Services	Percentage	Range of Prices
Financial Accounts	22%	$10–$1,000
Credit Card Information	13%	$.40-$20
Identity Information	9%	$1–$15
eBay Accounts	7%	$1–$8
Scams	7%	$2.5–$50/week for hosting $25 for design
Mailers	6%	$1–$10
Email Addresses	5%	$.83-$10/MB
Email Passwords	5%	$4–$30
Drop (request or offer)	5%	10%–50% of drop amount
Proxies	5%	$1.50–$30

(Complied from Miami Electronic Crimes Task Force and Symantec Global Internet Security Threat Report (2008)).

Nation-State Backed

Nations performing espionage against other nations do not ignore the potential for intelligence gathering via information technology systems. Sometimes this espionage takes the form of malware injection and system compromises such as the previously mentioned Titan Rain attack while other times it may take the form of electronic data interception of unencrypted e-mail and other messaging protocols. A number of nations have developed or are developing an information warfare capability designed to impair or incapacitate an enemy's Internet-connected systems, command-and-control systems, and other information technology capability [12]. These sorts of capabilities were demonstrated in 2007 against Estonia, allegedly by Russian sympathizers, utilizing a sustained series of denial-of-service attacks designed to make certain Websites unreachable as well as interfere with online activities such as e-mail and mission-critical systems such as telephone exchanges [13].

8. A BRIEF INTRODUCTION TO TCP/IP

Throughout the history of computing, there have been numerous networking protocols, the structured rules computers use to communicate with each other, but none have been as successful and become as ubiquitous as the Transmission Control Protocol/Internet Protocol (TCP/IP) suite of protocols. TCP/IP is the protocol suite used on the Internet and the vast majority of enterprise and government networks have now implemented TCP/IP on their networks. Due to this ubiquity almost all attacks against computer systems seen today are designed to be launched over a TCPI/IP network and thus the majority of intrusion detection and prevention systems are designed to operate with and monitor TCP/IP-based networks. Therefore, to better understand the nature of these technologies it is important to have a working knowledge of TCP/IP. While

a complete description of TCP/IP is beyond the scope of this chapter, there are numerous excellent references and tutorials for those interested in learning more [14,15]. Three features that have made TCP/IP so popular and widespread are [16]:

1. Open protocol standards that are freely available. This and independence from any particular operating system or computing hardware means TCP/IP can be deployed on nearly any computing device imaginable.
2. Hardware, transmission media and device independence. TCP/IP can operate over numerous physical devices and network types such as Ethernet, Token Ring, optical, radio, and satellite.
3. A consistent and globally scalable addressing scheme. This ensures that any two uniquely addressed network nodes can communicate (notwithstanding any traffic restrictions implemented for security or policy reasons) with each other even if those nodes are on different sides of the planet.

9. THE TCP/IP DATA ARCHITECTURE AND DATA ENCAPSULATION

The best way to describe and visualize the TCP/IP protocol suite is to think of it as a layered stack of functions, as shown in Figure 26.1.

Each layer is responsible for a set of services and capabilities provided to the layers above and below it. This layered model allows developers and engineers to modularize the functionality in a given layer and minimize the impacts of changes on other layers. Each layer performs a series of functions on data as it is prepared for network transport or received from the network. How those functions are performed internal to a given layer is hidden from the other layers and as long as the agreed upon rules and standards are adhered to with regards to

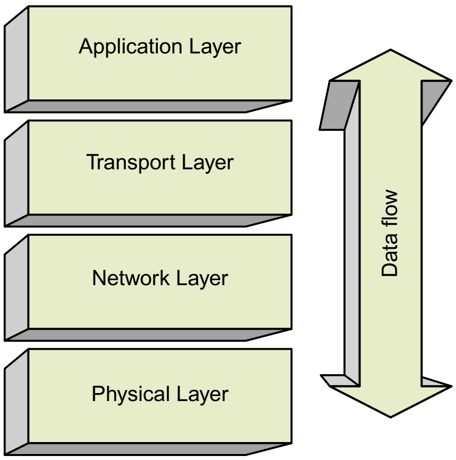

FIGURE 26.1 TCP/IP data architecture stack.

how data is passed from layer to layer, the inner workings of a given layer are isolated from any other.

The Application Layer is concerned with applications and processes, including those that users interact with such as browsers, e-mail, instant messaging and other network-aware programs. There may also be numerous applications in the Application Layer running on a computer system that interact with the network but users have little interaction with such as routing protocols.

The Transport Layer is responsible for handling data flow between applications on different hosts on the network. There are two Transport protocols in the TCP/IP suite: the Transport Control Protocol (TCP) and the User Datagram Protocol (UDP). TCP is a connection or session oriented protocol which provides a number of services to the above application such as reliable delivery via Positive Acknowledgement with Retransmission (PAR), packet sequencing to account for out-of-sequence receipt of packets, receive buffer management, and error detection. In contrast, UDP is a low-overhead, connectionless protocol that provides no delivery acknowledgement or other session services. Any necessary application reliability must be built into the application whereas with TCP, the application need not worry about the details of packet delivery. Each protocol serves a specific purpose and allows maximum flexibility to application developers and engineers. There may be numerous network services running on a computer system each built on either TCP or UDP (or, in some cases, both) so both protocols utilize the concept of *ports* to identify a specific network service and direct data appropriately. For example, a computer may be running a Web server and standard Web services are offered on TCP port 80. That same computer could also be running an e-mail system utilizing the Simple Mail Transport Protocol (SMTP) which is by standard offered on TCP port 25. Finally, this server may also be running a Domain Name Server (DNS) server on both TCP and UDP port 53. As can be seen, the concept of ports allows multiple TCP and UDP services to be run on the same computer system without interfering with each other.

The Network Layer is primarily responsible for packet addressing and routing through the network. The Internet Protocol (IP) manages this process within the TCP/IP protocol suite. One very important construct found in IP is the concept of an IP address. Each system running on a TCP/IP network must have at least one unique address for other computer systems to direct traffic to it. An IP address is represented by a 32-bit number which is usually represented as four integers ranging from 0 to 255 separated by decimals such as 192.168.1.254. This representation is often referred to as a *dotted quad*. The IP address actually contains two pieces of information in it: the network address and the node address. To know where the network address ends and the node address

begins a *subnet mask* is used to indicate the number of bits in the IP address assigned to the network address and is usually designated as a slash and a number such as '/24'. If the example address of 192.168.1.254 has a subnet mask of /24, then we know that the network address is 24 bits or 192.168.1 and the node address is 254. If we were presented with a subnet mask of /16 then we would know the network address is 192.168 while the node address is 1.254. Subnet masking allows network designers to construct subnets of various sizes ranging from two nodes (a subnet mask of /30) to literally millions of nodes (a subnet of /8) or anything in between. The topic of subnetting and its impact on addressing and routing is a complex one and the interested reader is referred to [14] for more detail.

The Physical Layer is responsible for interaction with the physical network medium. Depending on the specifics of the medium this may include functions such as collision avoidance, the transmission and reception of packets or datagrams, basic error checking, and so on. The Physical Layer handles all of the details of interfacing with the network medium and isolates the upper layers from the physical details.

Another important concept in TCP/IP is that of data encapsulation. Data is passed up and down the stack as it travels from a network-aware program or application in the Application Layer, is packaged for transport across the network by the Transport and Network Layer and eventually placed on the transmission medium (copper or fiber optic cable, radio, satellite, and so on) by the Physical Layer. As data is handed down the stack, each layer adds its own header (a structured collection of fields of data) to the data passed to it by the above layer. Figure 26.2 illustrates three important headers: the IP header, the TCP header, and the UDP header. The reader will note the various headers are where layer-specific

(sourced from Request for Comment (RFC) 791, 793, 768)

FIGURE 26.2 IP, TCP, and UDP headers.

constructs such as IP address and TCP or UDP port numbers are placed so the appropriate layer can access this information and act on the accordingly.

The receiving layer is not concerned with the content of the data passed to it, only that the data is given to it in a way compliant with the protocol rules. The Physical Layer places the completed packet (the full collection of headers and application data) onto the transmission medium for handling by the physical network. When a packet is received, the reverse process occurs. As the packet travels up the stack, each layer removes its respective header, inspects the header content for instructions on which upper layer in the protocol stack to hand the remaining data to, and passes the data to the appropriate layer. This process is repeated until all TCP/IP headers have been removed and the appropriate application is handed the data. The encapsulation process is illustrated in Figure 26.3.

To best illustrate these concepts, let us explore a somewhat simplified example. Figure 26.4 illustrates the various steps in this example. Assume a user, Alice, wishes to send an e-mail to her colleague Bob at Cool Company.com:

1. Alice launches her e-mail program and types in Bob's e-mail address, *bob@coolcompany.com*, as well as her message to Bob. Alice's e-mail program constructs a properly formatted SMTP-compliant message, resolves Cool Company's e-mail server address utilizing a DNS query, and passes the message to the TCP component of the Transport Layer for processing.
2. The TCP process adds a TCP header in front of the SMTP message fields including such pertinent information as the source TCP port (randomly chosen as a port number greater than 1024, in this case 1354), the destination port (port 25 for SMTP e-mail), and other TCP-specific information such as sequence numbers and receive buffer sizes.
3. This new data package (SMTP message plus TCP header) is then handed to the Network Layer and an IP header is added with such important information as the source IP address of Alice's computer, the destination IP address of Cool Company's e-mail server, and other IP specific information such as packet lengths, error-detection checksums, and so on.
4. This complete IP packet is then handed to the Physical Layer for transmission onto the physical network medium, which will add network layer headers as appropriate. Numerous packets may be needed to fully transmit the entire e-mail message depending on the various network media and protocols that must be traversed by the packets as they leave Alice's network and travel the Internet to Cool Company's e-mail server. The details will be handled by the intermediate systems and any required updates or changes to the packet headers will be made by those systems.
5. When Cool Company's e—mail server receives the packets from its local network medium via the Physical Layer, it removes the network frame and hands the remaining data to the Network Layer.
6. The Network Layer strips off the IP header and hands the remaining data to the TCP component of the Transport Layer.
7. The TCP process removes and examines the TCP header to, among other tasks, examine the destination port (again, 25 for e-mail), and finally hand the SMTP message to the SMTP server process.
8. The SMTP application performs further application specific processing as well delivery to Bob's e-mail application by starting the encapsulation process all over again to transit the internal network between Bob's PC and the server.

It is important to understand that network-based computer system attacks can occur at every layer of the TCP/IP stack and thus an effective intrusion detection and prevention program must be able to inspect at each layer and act accordingly. Intruders may manipulate any number of fields within a TCP/IP packet to attempt to bypass security processes or systems including the application-specific data, all in an attempt to gain access and control of the target system.

10. SURVEY OF INTRUSION DETECTION AND PREVENTION TECHNOLOGIES

Now that we have discussed the threats and those who pose them to information systems as well as examined

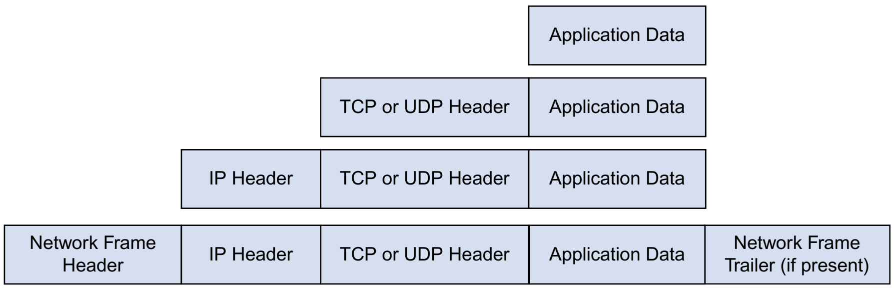

FIGURE 26.3 TCP/IP encapsulation.

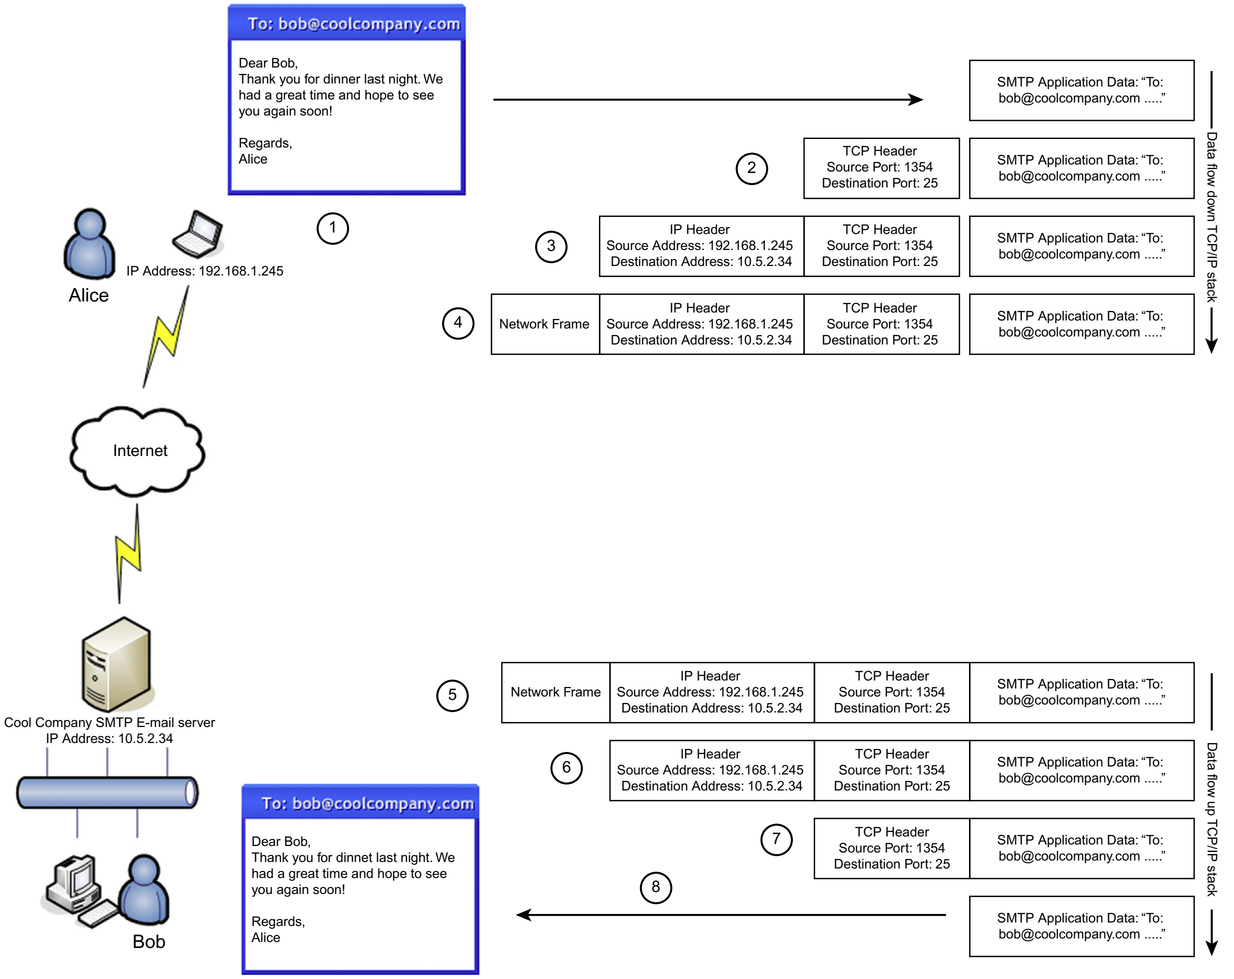

FIGURE 26.4 Application and network interaction example.

the underlying protocol suite in use on the Internet and enterprise networks today we are prepared to explore the various technologies available to detect and prevent intrusions. It is important to note that while technologies such as firewalls, a robust patching program and disk and file encryption can be part of a powerful intrusion prevention program these are considered static preventative defenses and will not be discussed here. In this section, we will discuss various dynamic systems and technologies that can assist in the detection and prevention of attacks on information systems.

11. ANTI-MALWARE SOFTWARE

We have discussed malware and its various forms previously. Anti-malware software, in the past typically referred to as anti-virus software, is designed to analyze files and programs for known signatures, or patterns, in the data that make up the file or program and indicates malicious code is present. This signature scanning is often accomplished in a multi-tiered approach where the entire hard drive of the computer is scanned sequentially during idle periods and any file accessed is scanned immediately to help prevent dormant code in a file that has not been scanned from becoming active. When an infected file or malicious program is found, it is prevented from running and either quarantined (moved to a location for further inspection by a system administrator) or simply deleted from the system. There are also appliance-based solutions that can be placed on the network to examine certain classes of traffic such as e-mail before being delivered to the end systems.

In any case, the primary weakness of the signature-based scanning method is that if the software does not have a signature for a particular piece of malware then the malware will be effectively invisible to the software and will be able to run without interference. A signature may not exist because a particular instance of the anti-malware software may not have an up to date signature database or the malware may be new or modified so as to

avoid detection. To overcome this increasingly common issue, more sophisticated anti-malware software will monitor for known-malicious behavioral patterns instead of, or in addition to, signature based scanning. Behavioral pattern monitoring can take many forms such as observing the system calls all programs make and identifying patterns of calls that are anomalous or known-malicious. Another common method is to create a white list of allowed known-normal activity and prevent all other activity or at least prompt the user when a non-while listed activity is attempted. While these methods overcome some of the limitations of the signature-based model and can help detect previously never seen malware, they come with the price of higher false positive rates and/or additional administrative burdens.

While anti-malware software can be evaded by new or modified malware, it still serves a useful purpose as a component in a defense-in-depth strategy, as illustrated in Figure 26.5. A well maintained anti-malware infrastructure will detect and prevent known forms, thus freeing up resources to focus on other threats, but it can also be used to help speed and simplify containment and eradication of a malware infection once an identifying signature can be developed and deployed.

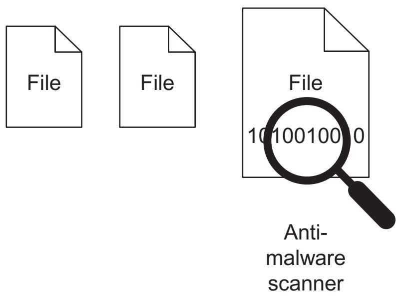

FIGURE 26.5 Anti-malware file scanning

12. NETWORK-BASED INTRUSION DETECTION SYSTEMS

For many years, network-based intrusion detection systems (NIDS) have been the workhorse of information security technology and in many ways have become synonymous with intrusion detection [17]. NIDS function in one of three modes: signature detection, anomaly detection, and hybrid. A signature-based NIDS operates by passively examining all the network traffic flowing past its sensor interface or interfaces and examines the TCP/IP packets for signatures of known attacks as illustrated in Figure 26.6.

TCP/IP packet headers are also often inspected to search for nonsensical header field values sometimes used by attackers in an attempt to circumvent filters and monitors. In much the same way that signature-based anti-malware software can be defeated by never before seen malware or malware sufficiently modified to no longer possess the signature used for detection, signature-based NIDS will be blind to any attack it does not have a signature for. While this can be a very serious limitation, signature-based NIDS are still useful due to most system's ability for the operator

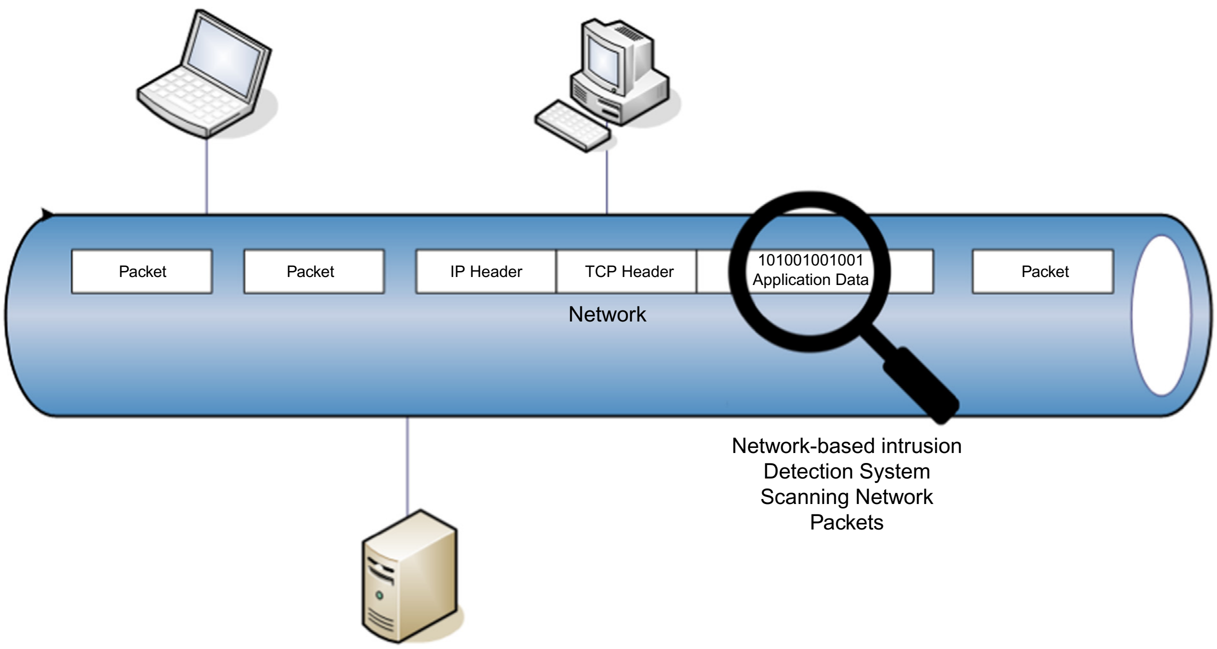

FIGURE 26.6 NIDS device scanning packets flowing past sensor interface.

to add custom signatures to sensors. This allows security and network engineers to rapidly deploy monitoring and alarming capability on their networks in the event they discover an incident or are suspicious about certain activity. Signature-based NIDS are also useful to monitor for known-attacks and ensure none of those are successful at breaching systems, freeing up resources to investigate or monitor other more serious threats.

NIDS designed to detect anomalies in network traffic build statistical or baseline models for the traffic they monitor and raise an alarm on any traffic that deviates significantly from those models. There are numerous methods for detecting network traffic anomalies but one of the most common involves checking traffic for compliance with various protocols standards such as TCP/IP for the underlying traffic and application layer protocols such as HTTP for Web traffic, SMTP for e-mail and so on. Many attacks against applications or the underlying network attempt to cause system malfunctions by violating the protocol standard in ways unanticipated by the system developers and which the targeted protocol handling layer does not deal with properly. Unfortunately, there are entire classes of attacks that do not violate any protocol standard and thus will not be detected by this model of anomaly detection. Another model commonly used is to build a model for user behavior and to generate an alarm when a user deviates from the 'normal' patterns. For example, if Alice never logs into the network after 9 pm and suddenly a logon attempt is seen from Alice's account at 3 am, this would constitute a significant deviation from normal usage patterns and generate an alarm. Some of the main drawbacks of anomaly detection systems are defining the models of what is normal and what is malicious, defining what is a significant enough deviation from the norm to warrant an alarm, and defining a sufficiently comprehensive model or models to cover the immense range of behavioral and traffic patterns that are likely to be seen on any given network. Due to this complexity and the relative immaturity of adaptable, learning anomaly detection technology, there are very few production-quality systems available today. However, due to not relying on static signatures and the potential of a successful implementation of an anomaly detection NIDS for detecting 0-day attacks and new or custom malware is so tantalizing that much research continues in this space.

A hybrid system takes the best qualities of both signature-based and anomaly detection NIDS and integrates them into a single system to attempt to overcome the weaknesses of both models. Many commercial NIDS now implement a hybrid model by utilizing signature matching due to its speed and flexibility while incorporating some level of anomaly detection to, at minimum, flag suspicious traffic for closer examination by those responsible for monitoring the NIDS alerts.

Aside from the primary criticism of signature-based NIDS their depending on static signatures, common additional criticisms of NIDS are they tend to produce a lot of false alerts either due to imprecise signature construction or poor tuning of the sensor to better match the environment, poor event correlation resulting in many alerts for a related incident, the inability to monitor encrypted network traffic, difficulty dealing with very high speed networks such as those operating at 10 gigabits per second, and no ability to intervene during a detected attack. This last criticism is one of the driving reasons behind the development of intrusion prevention systems.

13. NETWORK-BASED INTRUSION PREVENTION SYSTEMS

While NIDS are designed to passively monitor traffic and raise alarms when suspicious traffic is detected, network-based intrusion prevention systems (NIPS) are designed to go one step further and actually try to prevent the attack from succeeding. This is typically achieved by inserting the NIPS device inline with the traffic it is monitoring. Each network packet is inspected and only passed if it does not trigger some sort of alert based on a signature match or anomaly threshold. Suspicious packets are discarded and an alert is generated.

The ability to intervene and stop known attacks, in contrast to the passive monitoring of NIDS, is the greatest benefit of NIPS. However, NIPS suffers from the same drawbacks and limitations as discussed for NIDS such as heavy reliance on static signatures, inability to examine encrypted traffic, and difficulties with very high network speeds. In addition, false alarms are much more significant due to the fact that the NIPS may discard that traffic even though it is not really malicious. If the destination system is business or mission critical, this action could have significant negative impact on the functioning of the system. Thus, great care must be taken to tune the NIPS during a training period where there is no packet discard before allowing it to begin blocking of any detected, malicious traffic.

14. HOST-BASED INTRUSION PREVENTION SYSTEMS

A complementary approach to network-based intrusion prevention is to place the detection and prevention system on the system requiring protection as an installed software package. Host-based intrusion prevention systems (HIPS), while often utilizing some of the same signature-based technology found in NIDS and NIPS, also take advantage of being installed on the protected system to protect by monitoring and analyzing what other processes on the

system are doing at a very detailed level. This process monitoring is very similar to that which we discussed in the anti-malware software section and involves observing system calls, interprocess communication, network traffic, and other behavioral patterns for suspicious activity. Another benefit of HIPS is that encrypted network traffic can be analyzed after the decryption process has occurred on the protected system thus providing an opportunity to detect an attack that would have been hidden from a NIPS or NIDS device monitoring network traffic.

Again, as with NIPS and NIDS, HIPS is only as effective as its signature database, anomaly detection model, or behavioral analysis routines. Also, the presence of HIPS on a protected system does incur processing and system resource utilization overhead and on a very busy system, this overhead may be unacceptable. However, given the unique advantages of HIPS, such as being able to inspect encrypted network traffic, it is often used as a complement to NIPS and NIDS in a targeted fashion and this combination can be very effective.

15. SECURITY INFORMATION MANAGEMENT SYSTEMS

Modern network environment generate a tremendous amount of security event and log data via firewalls, network routers and switches, NIDS/NIPS, servers, anti-malware systems and so on. Envisioned as a solution to help manage and analyze all of this information, security information management (SIM) systems have since evolved to provide data reduction, to reduce the sheer quantity of information that must analyzed, and event correlation capabilities that assist a security analyst to make sense of it all [18]. A SIM system not only acts as a centralized repository for such data, it helps organize it and provides an analyst the ability to do complex queries across this entire database. One of the primary benefits of a SIM system is that data from disparate systems is normalized into a uniform database structure thus allowing an analyst to investigate suspicious activity or a known incident across different aspects and elements of the IT environment. Often an intrusion will leave various types of 'footprints' in the logs (see checklist: "An Agenda For Action For Logging Capabilities") of different systems involved in the incident and bringing these all together and providing the complete picture for the analyst or investigator is the job of the SIM.

Even with modern and powerful event correlation engines and data reduction routines, however, a SIM system is only as effective as the analyst examining the output. Fundamentally, SIM systems are a reactive technology, like NIDS, and because extracting useful and actionable information from them often requires a strong understanding of the various systems sending data to the SIM, the analysts skill set and experience become very critical to the effectiveness of the SIM as an intrusion detection system [19]. SIM systems also play a significant role during incident response as often times, evidence of an intrusion can be found in the various logs stored on the SIM.

16. NETWORK SESSION ANALYSIS

Network session data represents a high-level summary of 'conversations' occurring between computer systems [20]. No specifics about the content of the conversation such as packet payloads is maintained but various elements about the conversation are kept and can be very useful when investigated an incident or as an indicator of

An Agenda for Action for Logging Capabilities

Network-based intrusion detection and prevention systems (IDPSs) typically perform extensive logging of data related to detected events. This data can be used to confirm the validity of alerts, to investigate incidents, and to correlate events between the IDPS and other logging sources. Data fields commonly logged by network-based IDPSs include the following (check all tasks completed):

_____**1.** Timestamp (usually date and time).

_____**2.** Connection or session ID (typically a consecutive or unique number assigned to each TCP connection or to like groups of packets for connectionless protocols).

_____**3.** Event or alert type.

_____**4.** Rating (priority, severity, impact, confidence).

_____**5.** Network, transport, and application layer protocols.

_____**6.** Source and destination IP addresses.

_____**7.** Source and destination TCP or UDP ports, or ICMP types and codes.

_____**8.** Number of bytes transmitted over the connection.

_____**9.** Decoded payload data, such as application requests and responses.

_____**10.** State-related information (authenticated username).

_____**11.** Prevention action performed (if any).

_____**12.** Most network-based IDPSs can also perform packet captures. Typically this is done once an alert has occurred, either to record subsequent activity in the connection or to record the entire connection if the IDPS has been temporarily storing the previous packets.

suspicious activity. There are a number of ways to generate and process network session data ranging from vendor specific implementations such as Cisco's NetFlow [21] to session data reconstruction from full traffic analysis using tools such as Argus [22]. However the session data is generated, there are a number of common elements constituting the session such as source IP address, source port, destination IP address, destination port, timestamp information, and an array of metrics about the session such as bytes transferred and packet distribution.

Using the collected session information, an analyst can examine traffic patterns on a network to identify which systems are communicating with each other and identify suspicious sessions that warrant further investigation. For example, a server configured for internal use by users and having no legitimate reason to communicate with addresses on the Internet will cause an alarm to be generated if suddenly a session or sessions appear between the internal server and external addresses. At that point the analyst may suspect a malware infection or other system compromise and investigate further. Numerous other queries can be generated to identify sessions that are abnormal in some way or another such as excessive byte counts, excessive session lifetime, or unexpected ports being utilized. When run over a sufficient timeframe, a baseline for traffic sessions can be established and the analyst can query for sessions that don't fit the baseline. This sort of investigation is a form of anomaly detection based on high-level network data versus the more granular types discussed for NIDS and NIPS.

Another common usage of network session analysis is to combine it with the use of a honeypot or honeynet (see sidebar, "Honeypots and Honeynets"). Any network activity, other than known-good maintenance traffic such as patch downloads, seen on these systems is, by definition, suspicious as there are no production business functions or users assigned to these systems. Their sole purpose is to act as a lure for an intruder. By monitoring network sessions to and from these systems, an early warning can be raised without even necessarily needing to perform any complex analysis.

Honeypots and Honeynets

A honeypot is a computer system designed to act as a lure or trap for intruders. This is most often achieved by configuring the honeypot to look like a production system possibly containing valuable or sensitive information and providing legitimate services but in actuality neither the data or the services are real. A honeypot is carefully monitored and, since there is no legitimate reason for a user to be interacting with it, any activity seen targeting it is immediately considered suspicious. A honeynet is a collection of honeypots designed to mimic a more complex environment than one system can support [23].

17. DIGITAL FORENSICS

Digital forensics is the "application of computer science and investigative procedures for a legal purpose involving the analysis of digital evidence" [24]. Less formally digital forensics is the use of specialized tools and techniques to investigate various forms of computer-oriented crime including fraud, illicit use such as child pornography, and many forms of computer intrusions.

Digital forensics as a field can be divided into two subfields: network forensics and host-based forensics. Network forensics focuses on the use of captured network traffic and session information to investigate computer crime. Host-based forensics focuses on the collection and analysis of digital evidence collected from individual computer systems to investigate computer crime. Digital forensics is a vast topic and a comprehensive discussion is beyond the scope of this chapter and interested readers are referred to [25] for more detail.

In the context of intrusion detection, digital forensic techniques can be utilized to analyze a suspected compromised system in a methodical manner. Forensic investigations are most commonly used when the nature of the intrusion is unclear, such as those perpetrated via a 0-day exploit, but wherein the root cause must be fully understood either to ensure the exploited vulnerability is properly remediated or to support legal proceedings. Due to the increasing use of sophisticated attack tools and stealthy and customized malware designed to evade detection, forensic investigations are becoming increasingly common and sometimes only a detailed and methodical investigation will uncover the nature of an intrusion. The specifics of the intrusion may also require a forensic investigation such as those involving the theft of Personally Identifiable Information (PII) in regions covered by one or more data breach disclosure laws.

18. SYSTEM INTEGRITY VALIDATION

The emergence of powerful and stealthy malware, kernel-level rootkits, and so-called clean-state attack frameworks that leave no trace of an intrusion on a computer's hard drive have given rise to the need for technology that can analyze a running system and its memory and provide a series of metrics regarding the integrity of the system. System integrity validation (SIV) technology is still in its infancy and a very active area of research but primarily focuses on live system memory analysis and the notion of deriving trust from known-good system elements [26]. This is achieved by comparing the system's running state including the processes, threads, data structures, and modules loaded into memory to the static elements on disk that the running state was supposedly loaded from. Through a number of cross-validation processes,

discrepancies between what is running in memory and what should be running can be identified. When properly implemented, SIV can be a powerful tool for detecting intrusions, even those utilizing advanced techniques.

19. SUMMARY

It should now be clear that intrusion detection and prevention is not a single tool or product but a series of layered technologies coupled with the appropriate methodologies and skill sets. Each of the technologies surveyed in this chapter have their own specific strengths and weaknesses and a truly effective intrusion detection and prevention program must be designed to play to those strengths and minimize the weaknesses. Combining NIDS and NIPS with network session analysis and a comprehensive SIM, for example, helps to offset the inherent weakness of each technology as well as provides the information security team greater flexibility to bring the right tools to bear for an ever-shifting threat environment.

An essential element in a properly designed intrusion detection and prevention program is an assessment of the threats faced by the organization and a valuation of the assets to be protected. There must be an alignment of the value of the information assets to be protected and the costs of the systems put in place to defend them. The program for an environment processing military secrets and needing to defend against a hostile nation state must be far more exhaustive than that for a single server containing no data of any real value that must simply keep out assorted script kiddies.

For many organizations, however, their information systems are business and mission critical enough to warrant considerable thought and planning with regards to the appropriate choices of technologies, how they will be implemented, and how they will be monitored. Only through flexible, layered, and comprehensive intrusion detection and prevention programs can organizations hope to defend their environment against current and future threats to their information security.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Information security concerns itself with the integrity and availability of information systems and the information or data they contain and process.
2. True or False? Having physical access to a computer system allows an adversary to bypass most security protections put in place to prevent unauthorized access.
3. True or False? An insider is an individual who, due to their role in the organization, has some level of authorized access to the IS environment and systems.
4. True or False? An outsider is considered anyone who does not have authorized access privileges to an information system or environment.
5. True or False? Malware can be generally defined as "a set of instructions that run on your computer and make your system do something that allow an attacker to make it do what he wants it to do."

Multiple Choice

1. What is a self-replicating code that attaches itself to another program?
   - **A.** Worm
   - **B.** Virus
   - **C.** Backdoor
   - **D.** Trojan Horse
   - **E.** User-level Rootkit
2. What is a self-replicating code that propagates over a network, usually without human interaction?
   - **A.** Backdoor
   - **B.** Virus
   - **C.** Worm
   - **D.** Trojan Horse
   - **E.** User-level Rootkit
3. What is a program that bypasses standard security controls to provide an attacker access, often in a stealthy way?
   - **A.** Trojan Horse
   - **B.** Virus
   - **C.** Worm
   - **D.** Backdoor
   - **E.** User-level Rootkit
4. What is a program that masquerades as a legitimate, useful program while also performing malicious functions in the background?
   - **A.** Trojan Horse
   - **B.** Virus
   - **C.** Worm
   - **D.** Backdoor
   - **E.** User-level Rootkit
5. What is the Trojan/ backdoor code that modifies operating system software so the attacker can maintain privileged access on a machine but remain hidden?
   - **A.** Trojan Horse
   - **B.** Virus
   - **C.** Worm
   - **D.** Backdoor
   - **E.** User-level Rootkit

EXERCISE

Problem

How do intrusion detection systems (IDSs) work?

Hands-On Projects

Project

Why should an organization use an IDS, especially when they already have firewalls, anti virus tools, and other security protections on their system?

Case Projects

Problem

What are the different types of IDSs?

Optional Team Case Project

Problem

How do does one go about selecting the best IDS for their organization?

Chapter 27

TCP/IP Packet Analysis

Pramod Pandya
CSU Fullerton

1. THE INTERNET MODEL

This chapter will provide an overview of communication protocols that are necessary for transfer of data between or among communicating nodes (computers) connected through networks. An application program generates a continuous stream of data, which cannot be sent over a network as a continuous stream, but must be packetized per defined protocol and then sent over the network. Therefore, communicating nodes exchange packets of data over the network. Each of the packets is delineated with a header, contents, and a trailer. The header, the trailer, and the length of the packet are defined by the protocol that identifies the characteristic of the packet. A set of protocols are necessary for data communications between or among nodes. Hence a layered approach to data communication protocols is defined. This layered approach is known as the Internet model, which consists of five layers from top to bottom as illustrated in Figure 27.1. The Internet model is a submodel of the well-known Open System Interconnection (OSI) model with seven peer-to-peer layers. Communicating nodes on a network operate on a peer-to-peer basis using the protocols appropriate to a given layer.

Next, we will briefly review the logical functions of each of the layers from the Internet model before we provide a detailed discussion of each layer (see checklist: An Agenda for Action for the TCP/IP Layered Model). Let us examine the layers from bottom to top.

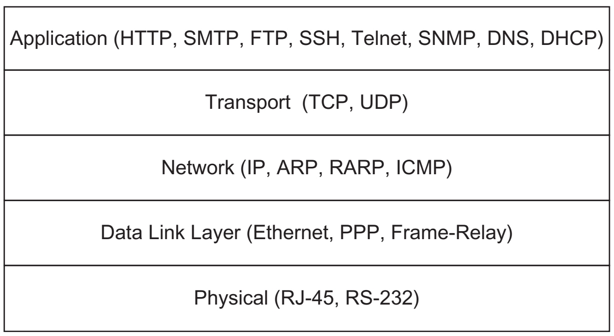

FIGURE 27.1 The Internet model.

The Physical Layer

The physical layer defines a commonly agreed standard for the mechanical, electrical, and functional specifications of the interface and the transmission media. The mechanical standard defines the kind of the connector, its size, and number of pins that are used to connect the computer to the bound medium (copper, or fiber), thus creating a network of computers. The electrical standard defines the allowable electrical voltage. The functional characteristic defines the binary logic that is used to represent the actual data bits. The reader should be aware that the data transmitted by the node attached to the network is transmitted serially in a synchronous manner to the other nodes on the network. This synchronous transmission requires that the data bits are organized to belong to packets. Thus even though data bits are placed on the medium one bit at a time, a bit on its own represents known information. Bits simply represent a predefined level of voltage. The physical layer is concerned with the following:

- Physical characteristics of interfaces and media
- Representation of bits
- Data rate
- Synchronization of bits
- Line configuration
- Physical topology
- Transmission mode

The Data Link Layer

The data link layer has two sublayers: the logical link control (LLC) and the media access control (MAC). The LLC is responsible for flow and error control. The MAC specifies how the node accesses the media, and the most commonly MAC for a Local Area Network (LAN) is carrier sense multiple access with collision detection

An Agenda for Action for the TCP/IP Layered Model

Knowing the fundamentals and how to diagnose/troubleshoot the network, with a focus on how to do an analysis of the TCP/IP packet, is vital to anyone who is in the networking field today, whether it be at the service provider level or enterprise level. This checklist focuses on the layered model approach to analyze the world of TCP/IP networking (check all tasks completed):

Layer 1: The Physical Layer:

_____**1.** Function of Layer 1
_____**2.** Transmission Type: Simplex/Half Duplex/Full Duplex
_____**3.** T1, DS1 Super Frame, DS1 Extended Super Frame
_____**4.** Wireless Physical Layer
_____**5.** Wired Ethernet Physical Layer
_____**6.** Wireless PHY Analysis
_____**7.** Wireless Wi-Fi Layers
_____**8.** 802.11 Fundamentals, BSS, ESS, Standards
_____**9.** Wireless Operations, Beacons, Management Frames
_____**10.** Wireless Data Capture

Layer 2: The Datalink Layer (Ethernet):

_____**11.** Ethernet Defined, Mechanisms and the OSI Model
_____**12.** Sublayers and Logical Link Control
_____**13.** Topologies
_____**14.** CSMA/CD and Full Duplex
_____**15.** Hubs and Switches
_____**16.** Ethernet Frame Formats
_____**17.** The MAC Address
_____**18.** ARP Protocol, Inverse, and Reverse ARP
_____**19.** Spanning Tree, RSTP Protocols
_____**20.** Ethernet Spanning Tree Analysis
_____**21.** VLANs and VLAN Trunking Protocol
_____**22.** Ethernet VLAN and VTP Analysis

Layer 3: The Network Layer —Internet Protocol (IP):

_____**23.** IP Protocol Functions, Format
_____**24.** IP Addressing, Reserved and Broadcast Addresses
_____**25.** IP Routing
_____**26.** Fragmenting Packets
_____**27.** IP Fragmentation
_____**28.** ICMP Protocol, Format, and Troubleshooting
_____**29.** ICMP Troubleshooting

Layer 4: The Transport Layer —TCP and UDP Protocols:

_____**30.** TCP Protocol Characteristics, Format
_____**31.** TCP Connection States
_____**32.** Three-Way-Handshake
_____**33.** TCP Sockets
_____**34.** TCP Segmentation
_____**35.** TCP Three-Way Handshake
_____**36.** Flow Control, Sliding Windows
_____**37.** Packet Loss, Re-transmission, and TCP Slow Start
_____**38.** Nagle Algorithm

(CSMA/CD, IEEE 802.3). The CSMA/CD is also known as Ethernet. All the nodes on a LAN share the medium for data transmission; thus two nodes on a LAN can create collision if they transmit bits at the same time. Ethernet is therefore a broadcast protocol, and the nodes are required to listen for signal level on the medium before transmitting data, thus avoiding collision. The wired Ethernet data transmission runs at 10, 100, and 1000 megabits per second (MBPS). The Ethernet protocol organizes the data bits in a packet known as the FRAME. The Ethernet frame is a data structure with a specific number of fields as illustrated in Figure 27.2. The data link layer has the following responsibilities:

- Framing
- Physical addressing
- Flow control
- Error control
- Access control

Preamble	SFD	Destination address	Source address	Length PDU	Data and padding	CRC

FIGURE 27.2 Ethernet frame.

Each field of the Ethernet Frame has the following characteristics.

- *Preamble*. The preamble contains seven bytes (56 bits) of alternating 0s and 1s that alert the receiving node to the coming frame and enable it to synchronize its input timing. The preamble is not part of the frame.
- *Start frame delimiter (SFD)*. The SFD field is 1 byte long (10101011) and signals the beginning of the frame. The last two one bits signal that the next field is the destination address.
- *Destination address (DA)*. The DA field is 6 bytes long and specifies the physical address of the destination node on the network.
- *Source address (SA)*. The SA field is 6 bytes long and specifies the physical address of the sending node on the network.
- *Length/type*. The length/type field is less than 1518; it is a length field and defines the length of the data field that follows. If the value of the field is greater than 1536, it defines the upper layer protocol that uses the services of the Internet.

- *Data.* The data field carries encapsulated data from the upper protocols. Its minimum length is 46 and a maximum 1500 bytes.
- *CRC.* This field is used to detect for a damaged Ethernet frame, using an algorithm known as Cyclic Redundancy Check.

Addressing in a LAN Select and Type an H3 Here

In a LAN, each node is assigned a physical address, also known as a MAC/Ethernet address. This address is unique to each of the nodes on the LAN and is 6 bytes (48 bits) long, which is burnt on the Ethernet card (also known as the network interface card, NIC). Ethernet is a byte-count protocol. A node on a LAN broadcasts a frame that is heard by all other nodes, and only the node whose Ethernet address matches with the DA in the Ethernet frame copies the frame into its buffer. If the DA address is a broadcast address (all 1's), then all the nodes on that LAN would copy the frame. Hackers can disguise the MAC address of their data packets to protect their identity by spoofing their MAC address. The utility that allows spoofing the MAC address is known as SMAC, which is available from Internet sites.

Benefits and Applications of Spoofing the MAC Address

Perform Security Vulnerability Testing, Penetration Testing on MAC Address-based Authentication and Authorization Systems (Wireless Access Points); as well as the following:

- Troubleshoot network problems.
- Troubleshoot ARP tables, routers, switching.
- Troubleshoot system problems.
- Test network management tools.
- Test incident response procedures on simulated network problems.
- Test Intrusion Detection Systems (IDS), whether they are Host-and Network-Based IDS.

(Disclaimer: Authorization to perform these tests must be obtained from the system owner(s).)

The Network Layer

The network layer consists of four protocols: the Internet Protocol (IP), Address Resolution Protocol (ARP), Reverse Address Resolution Protocol (RARP), and Internet Control Message Protocol (ICMP). The IP protocol is a connectionless protocol; hence it is not responsible for guaranteed delivery of data packets known as datagrams. The datagram encapsulates the data from the transport layer. The IP is responsible for addressing the datagram with the source and destination addresses of the nodes. It is also responsible for routing the datagram from the source node to the destination node, as well as making sure that the length of the datagram is compatible with the allowable packet length if the datagram is to travel through a Wide Area Network (WAN). In such a case, the router that connects a LAN to a WAN uses the Maximum Transfer Unit (MTU) packet length for the appropriate protocol such as X.25 or ATM running on the WAN. This function of the IP protocol is known as fragmentation, which is used by hackers to exploit any vulnerability in networks.

IP Packet Format

We will now consider the internals of the protocol and discuss its packet format and fields. IP uses 14 separate fields in the packet format. The fields fall into two basic categories. *Header management fields* handle the packet structure, version, data length, and protection of IP header. *Packet flow fields*, such as Type of Service, Fragmentation, and Time to Live, handle end-to-end delivery of packets. A detailed description of the fields of the IP Packet shown in Figure 27.3 is as follows:

- Version: 4 bits. The version of IP used.
- Header Length: This 4-bit field defines the total length of the datagram header in 4-byte words. The length of the header is from 20 to 60 bytes. With no Options, the header length is 20 bytes long.
- Differentiated Service (DS): 8 bits. This field was previously known as service type. Specifies how the upper layer protocol wants the current datagram to be handled.
- Total Length: 16 bits. The IP datagram length in bytes, including the IP header. Length of data = total length − header length.

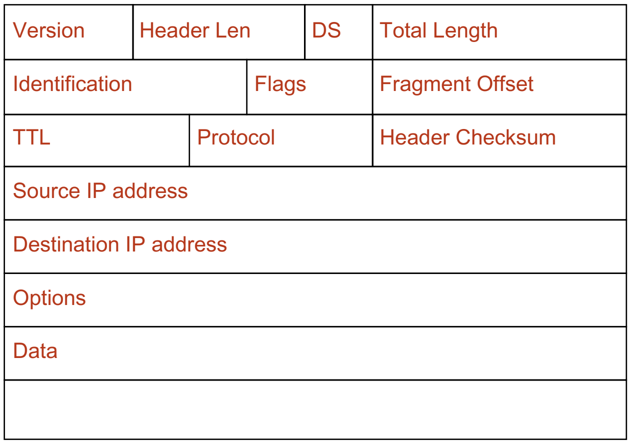

FIGURE 27.3 IP datagram.

- Identification: 16 bits. Contains an integer that identifies the current datagram.
- Flags: 3 bits. Consists of a 3-bit field of which the first bit is reserved. The second bit set to 1 means that the datagram must not be fragmented, and if it cannot pass through any network, then an ICMP error message is generated and the datagram is discarded. If the second bit is set to 0, then the datagram may be fragmented. The third bit set to 1 means that there are more fragments to follow. If the value of the third bit is set to 0, it means that this is the last or only fragment.
- Fragment Offset: 13 bits. Indicates the position of the fragment's data relative to the beginning of the data in the original datagram. It is the offset of the data in the original datagram measured in units of 8 bytes. Figure 27.4, Fragmentation Example, shows a datagram with data size of 4000 bytes fragmented into three fragments. The bytes in the original datagram are numbered 0 to 3999. The first fragment carries bytes 0 to 1399. The offset for this datagram is 0/8 = 0. The second fragment carries bytes 1400 to 2799; the offset value for this fragment is 1400/8 = 175. The third fragment carries bytes 2800 to 3999. The offset value for this fragment is 2800/8 = 350.
- Protocol: 8 bits. The upper-layer protocol that is the source or destination of the data.
- Header Checksum: 16 bits. Calculated over the IP header to verify header's correctness. It does not calculate the checksum over any of the data because that is covered by the Layer 2 CRC.
- Source IP address: 32 bits. The IP address of the sending host.
- Destination IP address: 32 bits. The IP address of the receiving host.
- Options.
- Data. IP datagrams can be sent with several options enabled. They are rarely used because most routers and firewalls do not allow them.

Figure 27.5, IPv4 Captured Packet, displays the contents of an IP packet. The fields we discussed are all displayed in the lower-left pane under the IPv4 Header. The Header length is 20 bytes; thus there are no IP Options. The data field is therefore 48 − 20 = 20 bytes long. The Flags indicate not to fragment the datagram.

Internet Protocol Addressing: Classful Addressing

The Internet Protocol (IP) provides an interface to an IP network, which is a logical, not physical, as provided by the data link layer protocol. The reader will note that the physical address is hard-coded on the network interface card, whereas the logical address is assigned to a node through the TCP/IP stack with programmable parameters. This feature permits designing an IP network with security parameters and makes it scaleable.

IP address ranges are categorized by a class of address. The first 3 bits of the 32-bit address determine the class of the address. Tables 27.1 and 27.2 show the bit settings and how IP addresses are classified. At the network (IP) layer, each device connected to the network must be assigned a unique IP address. We will restrict the overview to IPv4 (a 32-bit number).

Some IP network addresses per Table 27.3 are reserved (private-use), and hence can be used by anyone

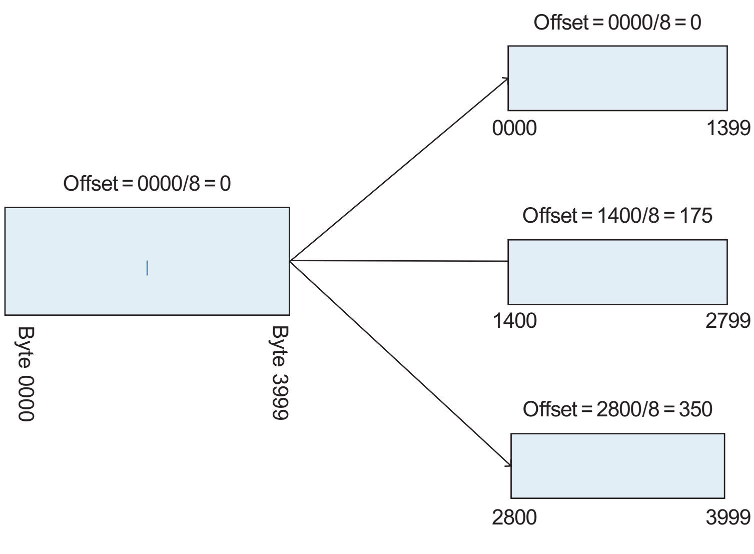

FIGURE 27.4 Fragmentation example.

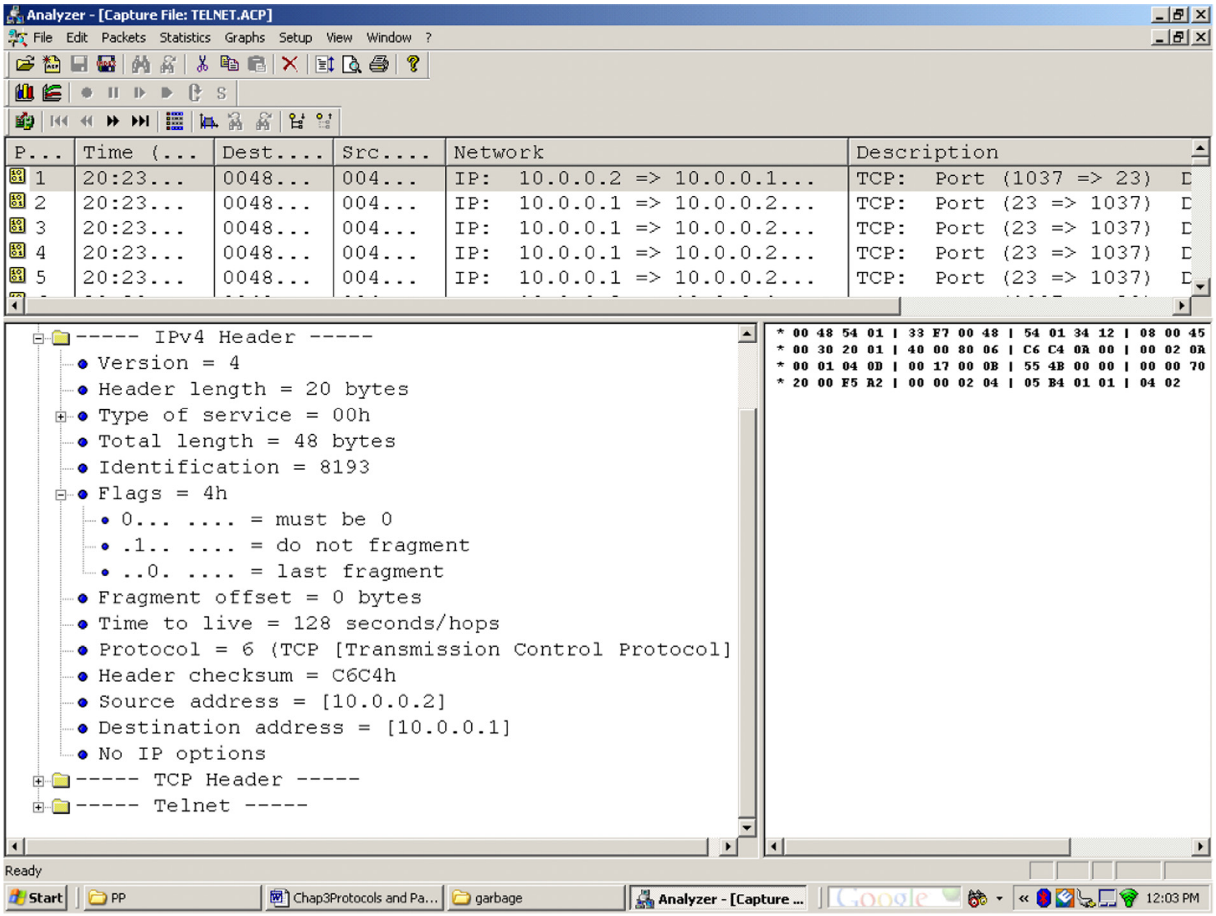

FIGURE 27.5 IPv4 captured packet.

TABLE 27.1 The Class in Binary Notation.

	First Byte	Second Byte	Third Byte	Fourth Byte
Class A	0			
Class B	10			
Class C	110			
Class D	1110			
Class E	11110			

TABLE 27.2 The Class in Decimal Notation.

	First Byte	Second Byte	Third Byte	Fourth Byte
Class A	1 TO 126			
Class B	128 TO 191			
Class C	192 TO 223			
Class D	224 TO 239			
Class E	240 TO 255			

without having to pay any fees. The rest of IP network addresses (public-use) have to be leased from an organization that keeps track of them.

In classful addressing (Table 27.4), an IP address is divided into Netid and Hostid. For each of the class, Table 27.4 represents the breakdown of bytes that represent the network id and the bytes that represent the host id.

Subnet Mask and Subnetting

Each class of a network address has an associated subnet mask as represented in Table 27.5. The IP protocol uses the subnet mask associated with the class of network address to extract the destination network address from the IP address of the destination node from the IP

TABLE 27.3 Reserved IP Address Ranges.

Address	Subnet Mask	Description
0.0.0.0	255.0.0.0	"This" Network
10.0.0.0	255.0.0.0	Private Network
127.0.0.0	255.0.0.0	Loopback
172.16.0.0	255.255.0.0	Private Network
192.168.1.0	255.255.255.0	Private Network

TABLE 27.4 Netid and Hostid.

	First Byte	Second Byte	Third Byte	Fourth Byte
Class A	Netid	Hostid	Hostid	Hostid
Class B	Netid	Netid	Hostid	Hostid

Class D	Multi	Class	add	Ress
Class E	Reserved	For	FUTURE	USE

TABLE 27.5 Subnet Mask.

	First Byte	Second Byte	Third Byte	Fourth Byte
Class A	255	0	0	0
Class B	255	255	0	0
Class C	255	255	255	0
Class D	1110			
Class E	11110			

datagram, and thus make a routing decision. IP is a routable protocol; hence IP datagrams can be routed. In classful routing, each interface on the network must be assigned a subnet mask corresponding to its class of network address. This scheme enables the interface in making the routing decision for the IP datagram.

Subnetting is a mechanism by which a given network address is divided into several logical groups of networks. The subnetting allows managing, supervising, and securing a large number of hosts, such that each of the subnets can be assigned a security policy independent of other subnets. Routing of IP datagram from one subnet to another subnet requires the subnets to be interconnected using a set of routers. These routers run a set of routing protocols.

Routing Internet Protocol (RIP)

RIP is an intradomain routing protocol used inside an autonomous system. It is based on distance vector routing. The number of networks that the datagram can travel before it reaches its destination is defined as the metric. This metric is also known as the hop count. Any route in an autonomous system using RIP cannot have more than 15 hops. This protocol is used by the routers to build the route table dynamically. RIP is implemented with all the MS-Windows Network Operating System, so that you can build a router using multiple network cards in a PC.

Open Shortest Path First (OSPF)

OSPF is an intradomain routing protocol based on link state routing. Its domain is autonomous. In link state routing, each node in the domain has the entire topology of the domain—the list of nodes and links, how they are connected.

Border Gateway Protocol (BGP)

BGP is based on a path vector routing algorithm. It is an interdomain routing protocol. In path vector routing, we assume that there is one node in each autonomous system that acts on behalf of the entire autonomous system. This node builds the routing table and advertises it to another such node in other autonomous systems. The idea is the same as the distance vector protocol except that only one node in each of the autonomous systems can communicate with other such nodes. RIP, OSPF, and BGP are implemented in Linux, so that you can build a router using a multiple network cards in a PC.

Address Resolution Protocol (ARP)

The IP protocol is capable of routing an IP datagram within the same IP segment (network address), or else it would need a router to route the datagram to a different IP segment (network address). The IP protocol uses the IP address specified in the destination IP field and the subnet mask to extract the destination IP network address to which the datagram must be routed. The IP protocol looks up in its routing table to determine if the destination network is directly accessible by the node or whether it needs the router to route the datagram to the destination network. The reader needs to be reminded that the Ethernet protocol on the host node needs the MAC address of the destination node to prepare the Ethernet frame. The host node has a routing table with IP addresses mapped to Ethernet addresses, known as ARP

(Address Resolution Protocol) cache. If the ARP cache does not have the MAC address mapped to its corresponding IP address entry, then an ARP request is generated by the host node to discover the MAC address corresponding to its IP address. If the destination node is on the same network, then this is resolved by the destination node upon its ARP reply and the destination MAC address corresponding to destination IP address is resolved. If the datagram needs to be routed out of the network address, then the IP protocol on the host node generates an ARP request to resolve the IP address to the MAC address of the Ethernet interface on the router to which the network segment connects. In such a case, the MAC address of the router interface is used as an intermediate MAC address. Once the IP address to the MAC address is resolved, the Ethernet protocol can next build the Ethernet frame and encapsulate the IP datagram. An ARP packet is directly encapsulated (bypassing IP datagram) into an Ethernet frame, as shown Figure 27.6.

The destination address in the Ethernet frame is all 1's, indicating that it is a broadcast address. Figure 27.7 illustrates the ARP packet format. Each field is described as follows:

- *Hardware type*. 16-bit field that defines the type of the network on which ARP is running. Ethernet is given the type 1.

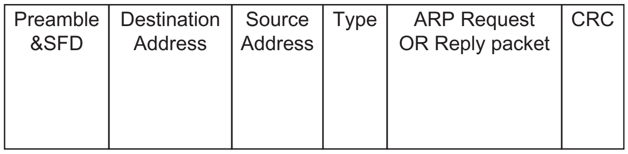

FIGURE 27.6 Encapsulation of an ARP packet in an Ethernet frame.

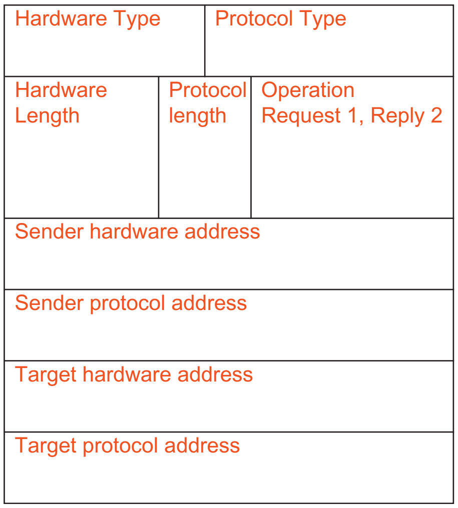

FIGURE 27.7 ARP packet.

- *Protocol type*. 16-bit field defines the protocol. For IPv4, the value of this field is 0×800.
- *Hardware length*. An 8-bit field that defines the length of the physical address, which is 6 bytes for the Ethernet address.
- *Protocol length*. An 8-bit field that defines the length of the logical address, which is 4 bytes for the IPv4 protocol.
- *Operation*. A 16-bit field defining the type of packet. Two packet types are ARP request (1) and ARP reply (2).
- *Sender hardware address*. The physical address of the sender node.
- *Sender protocol address*. The logical address of the sender node.
- *Target hardware address*. A field set to all 0s for an ARP request.
- *Target protocol address*. A field set to the IP address of the target node.

Figure 27.8 is a screen capture of an Ethernet frame using a sniffer program. Ping is executed from a node with an IP address 192.168.1.3 to a node with an IP address 192.168.1.4. The screen capture is divided into three panes. The upper pane displays six columns of information. You will observe that a packet number 6 is highlighted in the upper pane; it shows that an ARP request was generated with a source address 00045AA29675, destination address FFFFFFFFFFFF, which is a broadcast address. Under the description column in the upper pane, the node with an IP address 192.168.1.3 is broadcasting on the network to find the MAC address corresponding to the IP address 192.1681.4. The Ethernet frame in the lower-right pane shows a destination address of FFFFFFFFFFFF, which is a broadcast address.

Figure 27.9 represents the contents of the Ethernet frame and the ARP packet it encapsulates. The contents of the ARP packet displays the IP and MAC address of the sender's node. You will observe that the Target hardware address is 16 zeros, and the Target IP address is 192.168.1.4.

Reverse Address Resolution Protocol (RARP)

This protocol was designed so that a diskless node on a network can obtain an IP address given its physical address. This protocol has been replaced in terms of its usage by BOOTP and DHCP.

Internet Control Message Protocol (ICMP)

ICMP messages are encapsulated inside IP datagrams. ICMP is used for controlling the flow of data in the network, for reporting errors, and for performing diagnostics.

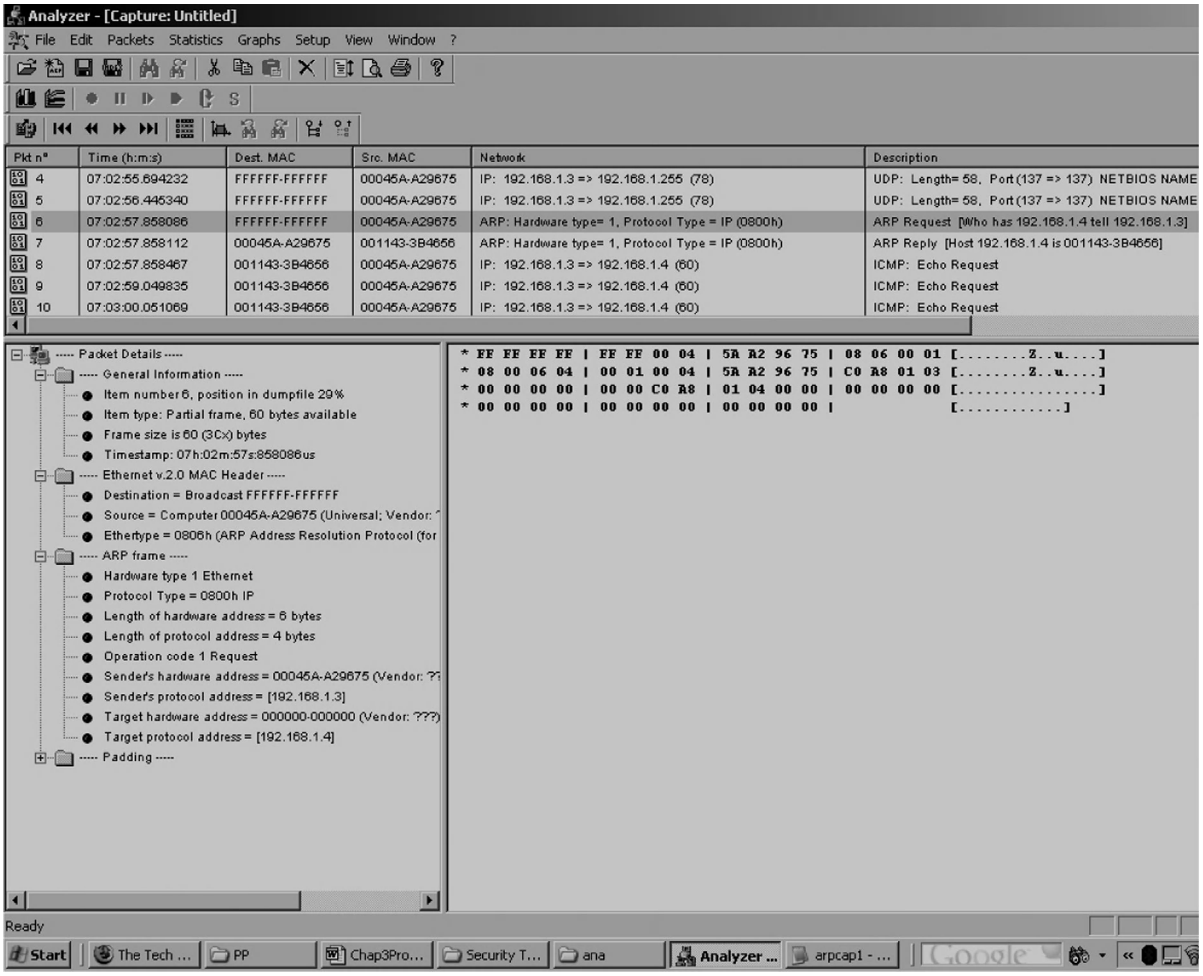

FIGURE 27.8 Captured Ethernet frame.

ICMP messages are divided in two categories: error-reporting messages (Figure 27.10) and query messages (Figure 27.11).

A very important troubleshooting tool within the ICMP protocol is ping, the packet Internet Groper. The ping command is used to verify connectivity with another host on a network. The ping command uses a series of echo requests and echo reply messages to query the status of a node on a network. The ping command can be exploited by a would-be hacker to check and monitor the status of nodes on a network before launching any attack. The current practice is to turn off a response to an echo request, thus effectively hiding the node from external users of the network.

The Transport Layer

The Transmission Control Protocol (TCP) is a transport layer protocol that provides for a connection-oriented, reliable service to applications. A connection-oriented protocol establishes a connection, manages the data transfer, and terminates the connection. Thus TCP provides end-to-end connectivity using a virtual connection between the endpoints; therefore all the data segments are sent over this same virtual path. In addition, TCP uses flow, error, and congestion control to manage transfer of data between the two endpoints. TCP offers full-duplex and multiplex service to applications. TCP uses IP address and port number (16-bit number) to identify the sending and receiving processes, respectively. The combination of IP address and port number is called a socket, and a TCP connection is uniquely identified by the two end sockets. The data generated by an application are encapsulated in TCP segments. Some of the most common applications and their port numbers are illustrated in Figure 27.12. Figure 27.13 shows the layout of the TCP header.

What follows is a description of a TCP header per Figure 27.13. This is extremely useful for decoding TCP

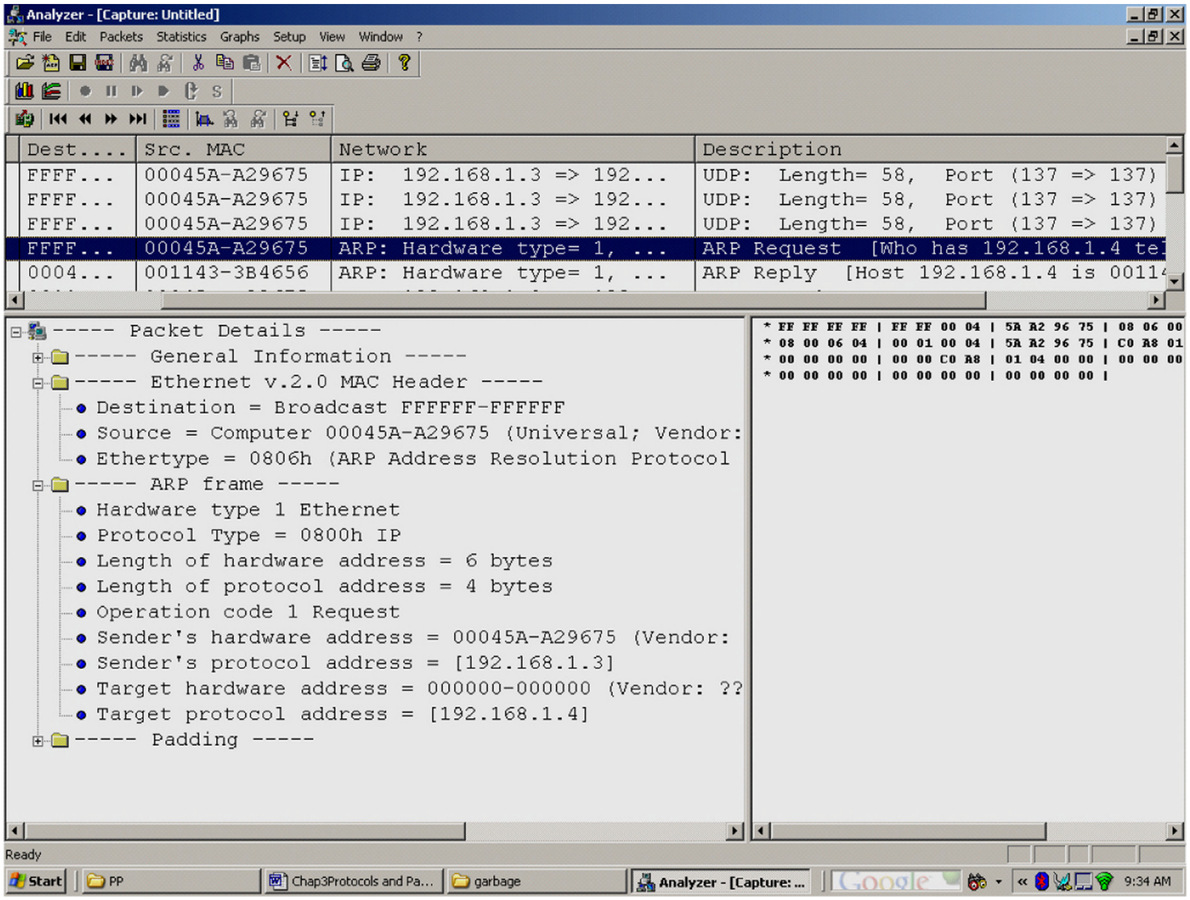

FIGURE 27.9 Contents of an ARP packet.

Type	Message
3	Destination unreachable
4	Source quench
11	Time exceede
12	Parameter problem
5	Redirection

FIGURE 27.10 Error-reporting messages.

Type	Message
8 or 0	Echo request or reply
13 or 14	Timestamp request or reply
17 or 18	Address mask request reply
10 or 9	Router solicitation or advertisement

FIGURE 27.11 Query messages.

segments, if you are to become an expert in the field of network intrusion, detection, and prevention:

- *Source Port Number*. 16-bit port number on the source host.
- *Destination Port Number*. 16-bit port number on the destination host.
- *Sequence Number*. This 32-bit field identifies the byte in the stream of data from the sending TCP to the receiving TCP. It is the sequence number of the first byte of data in this segment represents.
- *Acknowledgment Number*. This 32-bit field contains the next sequence number that the destination node wants to receive.
- *Header Length*. 4 bits. The length of the header is 32-bit words.

- *Reserved*. 6 bits.
- *Flags:* There are 6 bits for flags.
- *URG*: If the first bit is set, an urgent message is being carried.
- *ACK*: If the second bit is set, the acknowledgment number is valid.

7	Echo
23	Telnet
20,21	FTP
25	SMTP
53	DNS
67,68	DHCP
80	HTTP
110	POP3
445	SMB
1701	L2TP
1720	VoIP

FIGURE 27.12 Common applications and their port numbers.

- *PSH*: If the third bit is set, it is notification from the sender to the receiver that the receiver should pass all the data to the application quickly.
- *RST*: If the fourth bit is set, it signals a request to reset the TCP connection.
- *SYN:* The fifth bit of the flag field of the packet is set when initiating a connection.
- *FIN*: The sixth bit is set to terminate a connection.
- *Window Size*. This field defines the size of the window, in bytes that a receiver can accept. The length of this field is 16 bits; hence the maximum size of the window is 65,535 bytes.
- *Checksum*. This 16-bit field contains the checksum.
- *Urgent Pointer*. This 16-bit field, which is valid only if the URG flag is set, is used when the segment contains urgent data.
- *Options*. Up to 40 bytes of optional information in the TCP header.

Figure 27.14 displays a screenshot of a captured TCP segment. This segment has a SYN set to 1, indicating that the node with an IP address of 10.0.0.2, port number 1037, is attempting to establish an active TCP connection, with IP address 10.0.0.1 at a port number 23. The Acknowledgment field has a value of zero.

A TCP Connection—Three-way Handshaking

A unique sequence of three data packets are exchanged at the beginning of an active TCP connection as illustrated in Figure 27.15:

- The client initiates a connection by sending a synchronizing (SYN) packet.
- The server responds with a SYN + ACK packet.

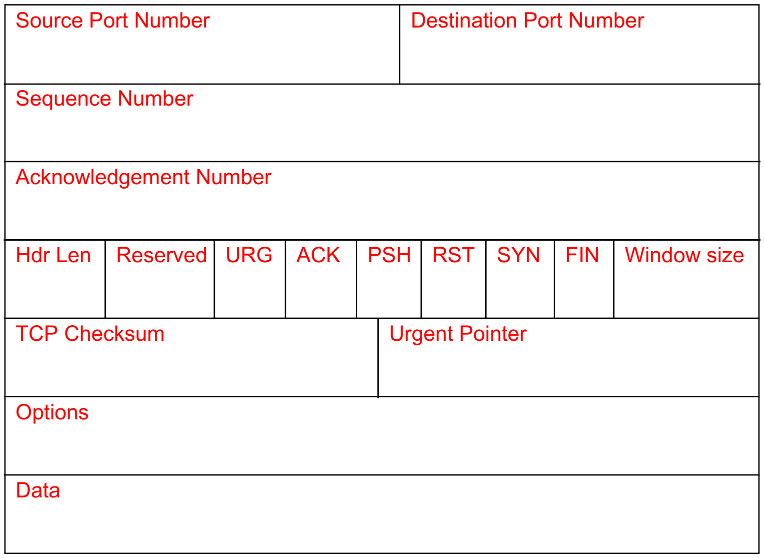

FIGURE 27.13 TCP header.

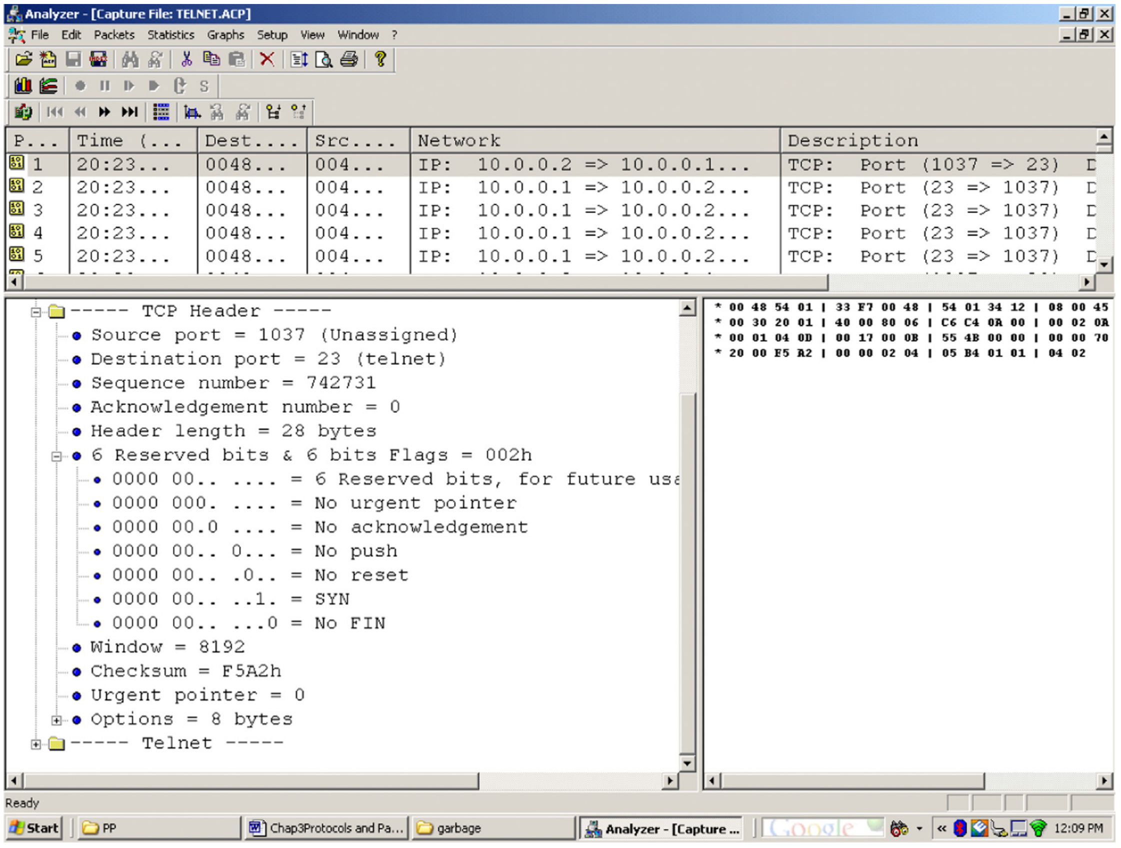

FIGURE 27.14 A captured screenshot of a TCP segment.

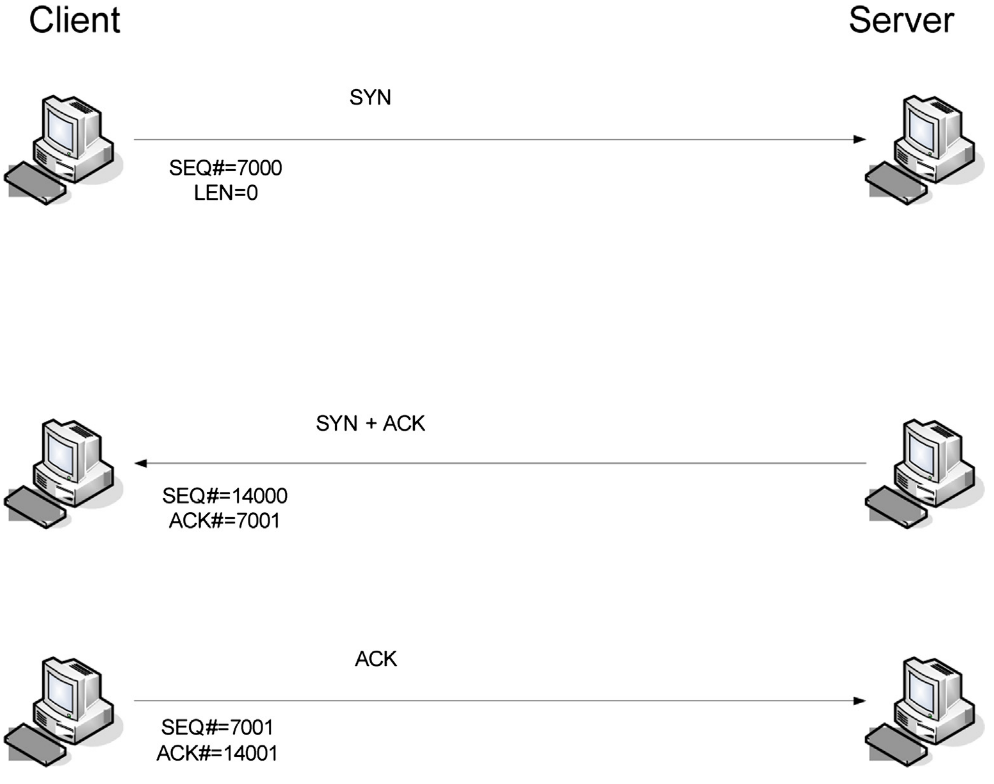

FIGURE 27.15 TCP connection—Three-way handshake.

- Finally the client acknowledges the SYN + ACK packet with its own ACK packet.

Thus an active TCP connection is established, and the two nodes can exchange data.

State Transition Diagram

To keep track of all the different events happening during connection establishment, connection termination, and data transfer, the TCP software is implemented as a finite state machine. At any one moment, the machine is in one of the states. It remains in that state until an event takes place. The event can change the state, and perform predefined action. Transition states for TCP protocol are given in Figure 27.16. Using netstat utility, you can discover the state of a TCP connection between two nodes. This information could be of help in network intrusion detection.

Maximum segment lifetime (MSL) is the maximum time a segment can exist in the Internet before it is dropped. The common value for MSL is between 30 and 60 seconds.

Connection Termination—In a three-way handshake

The client sends a FIN packet to the server; the server responds with FIN + ACK packet; and the client sends a ACK packet to confirm the receipt of the FIN + ACK packet. This would lead to the closing of the TCP connection.

Half-Close

An example of a Half-Close TCP session is when a client sends all the data to a server. At this point, the client closes its port on an outbound direction, but the inbound port is still kept open to receive the data.

Connection Reset

An RST segment can be sent by a receiving node to a sending node to the following:

- Deny a connection.
- Abort an existing connection.
- Terminate an idle connection.

SYN Flooding Attack

The full TCP connection establishment procedure is susceptible to a serious security flaw. A node can continuously send SYN segments to a server. This server in turn responds with SYN + ACK segments. During this process, the resources on the server get overloaded, leading

State	Description
CLOSED	No connection
LISTEN	Waiting for SYN
SYN-SENT	SYN sent; waiting for ACK
SYN-RECVD	SYN+ACK sent; waiting for ACK
ESTABLISHED	Connection established; data transfer in progress
FIN-WAIT-1	First FIN sent; waiting for ACK
FIN-WAIT-2	ACK to first FIN received; waiting for second FIN
CLOSE-WAIT	First FIN received, ACK sent; waiting for application to close
TIME-WAIT	Second FIN received, ACK sent; waiting for 2MSL time-out
LAST-ACK	Second FIN sent; waiting for ACK
CLOSING	Both sides have decided to close simultaneously

FIGURE 27.16 State Transitions for TCP.

to the server crash. This results in denial-of-service (DOS) attack.

User Datagram Protocol (UDP)

UDP is a transport layer protocol that provides a connectionless, unreliable service to applications. Each application that makes a call to a UDP service uses UDP port numbers to open a socket for service from a server node.

The Application Layer

Some of the Internet-based applications are vulnerable to attack by hackers. The reason for this is that the TCP/UDP port numbers where services are available are attacked to penetrate the network. To secure the networks from unauthorized users, firewalls are built around networks, and a minimum number of ports are kept open. Additionally, intrusion detection systems (IDS) are placed on the networks to monitor for anomalous traffic pattern.

Dynamic Host Configuration Protocol (DHCP)

The DHCP application has two components: a client, and a server. In an IP network, a DHCP server is configured to assign IP addresses to clients upon a request. In such a case, a DHCP client uses the UDP protocol to broadcast a request for an IP address. A DHCP server then might respond with an IP address. This IP address is leased for a fixed duration of time to the client.

Domain Name Server (DNS)

Nodes on an Internet when accessing Web service need to resolve the domain name to an IP address. This process is known as name resolution, whereby the client node uses the UDP protocol to broadcast for name resolution. If a DNS server is attacked, then the organization that relied on the DNS for name resolution is prevented from providing services to its client. If the top-level DNS servers are attacked, then most of the Internet becomes inaccessible, resulting in millions of dollars of loss of revenue. This is a result of a DNS server overloaded with name resolution queries. The most serious attack could be when a DNS session is hijacked, resulting in directing clients to unauthorized Web sites, leading to loss of confidence in E-commerce- based activities.

Traceroute

The traceroute in UNIX or tracert in Windows can be used to trace the route of a packet from source to destination node. The traceroute program uses two ICMP messages, time exceeded and destination unreachable, to find the route of a packet.

IpConfig

IpConfig is a Windows-based utility that displays the configured TCP/IP stack parameters such as the node's IP address, subnet mask, the Default Gateway's IP address, and the DNS's IP address. In addition, it also displays whether the IP address is static or a leased IP address.

Ping

Ping is a utility that allows you query the status of a remote node on a network. If the node is accessible, then the node responds to the query, which uses ICMP protocol.

Netstat

Netstat is a utility that displays protocol statistics with TCP/IP connections and port numbers. The utility will display the dynamic status of TCP/UDP ports.

2. SUMMARY

This chapter reviewed the significance of the TCP/IP stack in data networking. You should be able to examine the TCP/IP packet, analyze it, and explain the applications that are using the TCP/IP stack. The material in this chapter forms a building block for network intrusion detection. The exercises at the end of the chapter allow you to practice with the utilities on a network to reinforce the TCP/IP protocol concepts.

So, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The physical layer defines a commonly agreed standard for the mechanical, electrical, and the functional specifications of the interface and the transmission media.
2. True or False? The data link layer has two layers: the logical link control (LLC), and the media access control (MAC).
3. True or False? In a LAN, each node is assigned a physical address, also known as a MAC/Ethernet address.
4. True or False? The network layer consists of three protocols: The Internet Protocol (IP), the Address Resolution Protocol (ARP), and the Internet Control Message Protocol (ICMP).

5. True or False? The Internet Protocol (IP) provides an interface to an IP network, which is logical, not physical, as provided by the data link layer protocol.

Multiple Choice

1. What are categorized by a class of address?
   A. Worms
   B. Viruses
   C. IP address ranges
   D. Trojan horses
   E. User-level rootkits
2. Each class of a network address has an associated __________________?
   A. backdoor
   B. virus
   C. subnet mask
   D. Trojan horse
   E. user-level rootkit
3. What is an intradomain routing protocol used inside an autonomous system?
   A. Trojan horse
   B. Virus
   C. RIP
   D. Backdoor
   E. User-level rootkit
4. What is an intradomain routing protocol based on link state routing?
   A. Trojan horse
   B. Virus
   C. OSPF
   D. RIP
   E. User-level rootkit
5. What is based on a path vector routing algorithm?
   A. OSPF
   B. RIP
   C. Worm
   D. Backdoor
   E. BGP

EXERCISE

Problem

Explain how an organization can detect that the other end of a TCP/IP connection has crashed? Can the organization use keepalives for this?

Hands-On Projects

Project

Explain what is the full form of the OSI and TCP/IP model.

Case Projects

Problem

Explain how applications coexist over TCP and UDP.

Optional Team Case Project

Problem

Explain the role of TCP/IP in data transmission from source to destination?

Chapter 28

The Enemy (The Intruder's Genesis)

Dr. Pramod Pandya
CSU Fullerton

1. INTRODUCTION

In last few years, we have read and experienced the nature of such threats, resulting in loss of credit-card numbers, Social Security numbers, passwords, and other sensitive information. Security for the network has grown from a simpleminded approach to a multilevel approach, depending on the complexity of the network. As the number of Intranets connected to the Internet has grown, threat to network security has progressed from simple need for network security engineers to need for information security engineers. The primary function of network security engineers was to design network architecture to secure and protect network resources from unauthorized users, namely, hackers. The goal of information security engineers was to define and design the information architectural infrastructure to secure and protect information resources from being stolen by unauthorized users, namely hackers. Why then the need for a cybersecurity engineer? We have now seen that the Internet has more than a couple of billion users connecting to it from all over the world. Since all these users are not from one nation, it does pose a much greater security as the network traffic enters and leaves at the nation boundaries. Hence the Internet has morphed into a cyberspace and thus a need for a cybersecurity engineer. The reader can appreciate that the "Enemy" is not a just a hacker bounded by the nation-state boundary, but can be just from anywhere in cyberspace!

The latest incident-response report from the Industrial Control Systems Cyber Emergency Response Team (ICS-CERT)—part of the Department of Homeland Security (DHS)—warns of ongoing cyberattacks against the computer networks of U.S. natural gas pipeline companies. Cybersecurity experts believe that attacks on the critical commercial and public infrastructure will increase more rapidly in the future economic wars as the nation-states compete for natural resources and intelligence.

At the other extreme in the cyberspace is social media networking, which has dominated the conversation. The young and the mature alike all have accounts on Facebook to connect with each other. Facebook has a vital interest in making sure that its clientele feel confident about sharing their experiences and personal moments with their friends. Sharing becomes a lot less appealing when there is a risk of contagion. A growing number of companies have created their presence on Facebook and would want to make sure that the users on the Facebook would feel safe and confident to click on links that would direct them to a company's e-commerce site for marketing, customer support, and product reach. Presently, more information about individuals and companies has been made publicly available on Facebook, LinkedIn, Twitter, and other social media Web sites (cyberspace) than ever before. Social media sites can be used by companies to gather information about their competitors, and by hackers to exploit the information, the passwords, and much more.

A host of software-based hacking tools or toolkits are available freely from the various Web sites on the Internet. Hacker would initially take a survey of a network, scan for network devices, then look for open ports on those network devices, take an audit of available sensitive information on the vulnerable network devices, and finally design an attack plan to secure the sensitive information. Of course, this approach to compromise the network is designed so that the trace back to the hacker is lost in the maze of the Internet. It is not possible to completely secure the network (see Figure 28.1) against hackers, as most networks have at least one open port that permits communications with the rest of the Internet. This is the dilemma facing all network security professionals: how to safeguard the network from unauthorized access. The following steps are undertaken by those intending to hack a network:

- Gather information about nodes on the target network.
- Look for vulnerabilities in the target network—"holes."

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00028-3

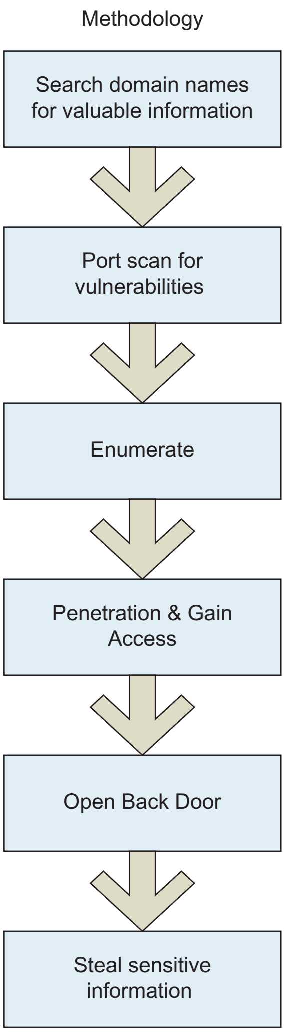

FIGURE 28.1 The six-step process necessary to gain control of a network.

- Exploit the "holes" to access the nodes in the target network.
- Secure access to the target network, without leaving the traces behind, for launching future attacks on the target network, or third-party networks.

Figure 28.1 shows the six-step process necessary to gain control of a network.

2. ACTIVE RECONNAISSANCE

The first step involves searching for Internet domain names, to help to identify those entities that would hold valuable information worth gaining access to. The next step is to map the domain names to network addresses, and finally map out the detail infrastructure of that network. Now we can begin to discover IP addresses of the network nodes and attempt to identify DNS servers, database servers, email servers, and Web servers. These various servers would hold the sensitive information of value. The next phase would be to place the DNS servers, email, and Web servers and database servers on the network and reproduce a complete network, including its functional specification. Once the target network is mapped out, we will use network-based tools to get all the information about that server, and then make a preparation to design a scheme to attack the network.

The domain name registered by the target corporate network can be found by entering the organization's domain name in a search at www.internic.net/whois.html. Thus, we can learn addresses for the target networks' DNS servers, Web servers, and email servers. The GFI Languard NSS software has a utility "whois" that easily allows discovering all the information regarding a domain name registered to a corporate network. DNS Zone transfers refer to learning about the servers and their IP addresses from zone files. Information collected is used to determine what TCP and or UDP services such as HTTP, SMTP, or FTP are in either "listening," "wait," or "closed" state, including the types of operating system and applications currently in use.

The examples of port scanning, and enumeration illustrated in this chapter were obtained using the network in Figure 28.2. The network consists of the following computers:

- kailash a Windows 2000 server—Domain PANDYA
- kalidas a Windows XP workstation
- nanjun a Linux server

Network Mapping

Network mapping (see Figure 28.3) is the process of discovering information about the topology of the target network, thus finding the IP addresses of gateways, routers, email, Web, FTP servers, and database servers. The next step is to sweep the target network to find live nodes by sending ping packets and waiting for response from the target nodes. ICMP messages can be blocked, so an alternative is to send a TCP or UDP packet to a port such as 80 (http) that is frequently open, and live machines will send a SYN-ACK packet in response. Once the live nodes are mapped, standard utility such as traceroute can provide additional information about the network topology by discovering the paths taken by packets to each host, which provides information about the routers and gateways in the network and the general network layout.

The screenshot in Figure 28.3 is obtained using a network security scanner from GFI Languard (http://www.gfi.com). This software is a commercial product, but a trial version 6.0 can be downloaded for 14 days.

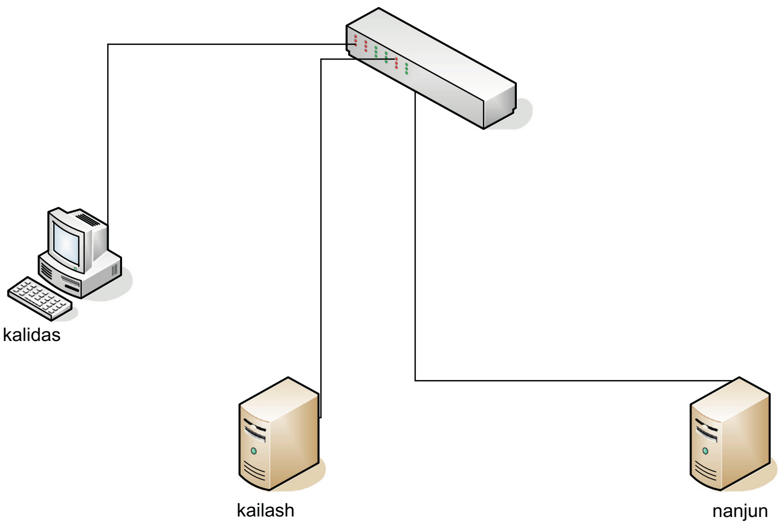

FIGURE 28.2 Switched Ethernet network.

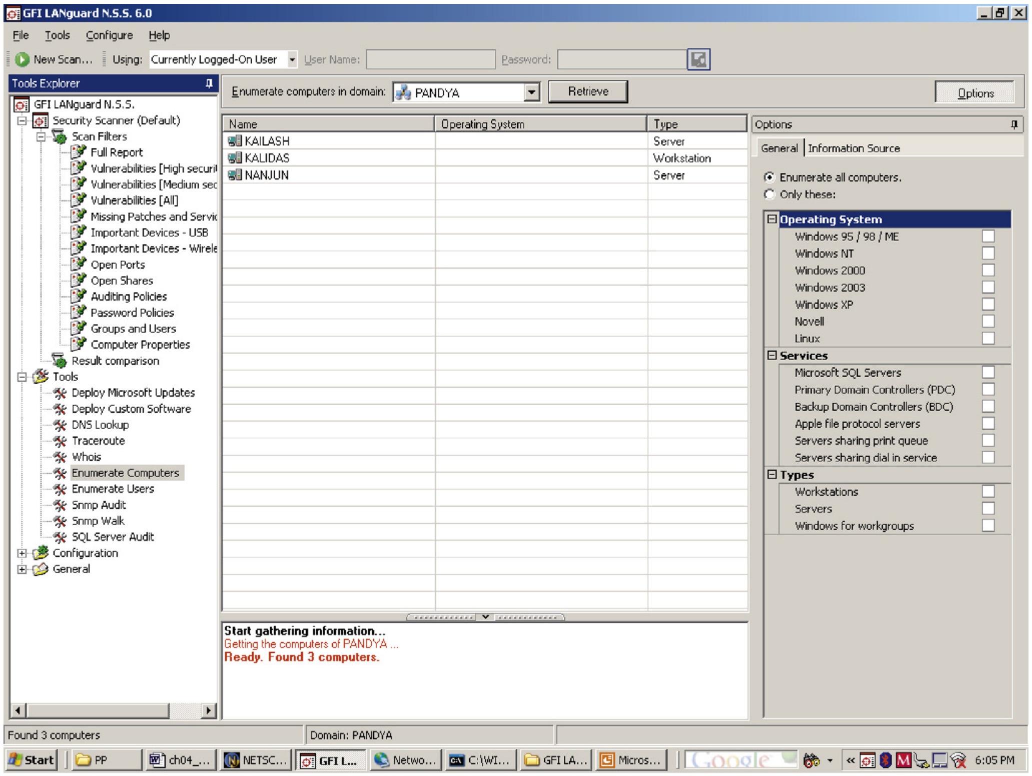

FIGURE 28.3 Network mapping of computers in Figure 28.2.

Nmap

The Nmap main page is described as a security/network exploration tool and port-scanner. The basic command line syntax to invoke Nmap is as follows:

- nmap [scan type(s)] [options] {target specification}
- Nmap has a huge list of command-line options, generally categorized into target specification, host listing, port specifications, service identification, scan technique, scripted scans, and output options. Some of the Nmap switches only work when run as the root (superuser).
- nmap -sL 192.168.1.0/24—Lists all the hosts scanned (all responding IPs in the subnet from 192.168.1.1 to 192.168.1.254).
- nmap -p80,443 192.168.1.10-20—Scans the IP address range looking for open ports 80 and 443.

- nmap -p T:80,8080,6588,800 172.16.0.1/22 — Scans all hosts between 172.16.0.1 and 172.16.3.254, looking for open TCP ports 80, 8080, 6588, and 800 (the default listening ports for various proxy servers).
- nmap -sP 192.168.1.10,20 — Ping scans two hosts in a fast scan.
- nmap -PN 192.168.1.0/29 — Scans all the hosts in the 192.168.1.1 to 192.168.1.6 range. Sometimes host-based firewalls deny ping requests, and it is difficult to scan such hosts. The `-PN` scan is useful in such cases; it scans the hosts assuming them to be online.
- nmap -A -F 192.168.1.1 — Detects target OS and services running on it, in fast-scan mode.

Idlescan

This scan will probe 192.168.1.95 while pretending that the scan packets come from another host; the target's logs will show that the scan originated from 192.168.1.10. This is called a zombie host.

Zombie hosts are those controlled by other hosts on the network. Not all hosts can be used as zombies, as certain conditions are required to be met before this is possible. (Using packages such as hping may enable you to find a zombie host on the network.) The `-v` switch increases the verbosity of the output.

Decoy Host

This command is especially useful while testing IDS/IPS. The `-sS` option will perform a SYN scan on the target host. While doing so, it will spoof the packet contents to make the target host see them as coming from the specified (`-D`) decoy hosts. The `-sI` and `-D` switches can't be combined, for obvious reasons.

Now, a word of caution: Be careful not to cause an unintended denial-of-service (DoS) attack while using the `-D` option. To understand how this could happen, we need to know how a TCP handshake operates. TCP, being a connection-oriented protocol that guarantees delivery of packets, operates with a three-way handshake:

- The client initiates the communication by a SYN.
- The server acknowledges with a SYN-ACK.
- The client again sends an ACK, and now they can communicate.

If the `-D` switch is used, and there is a live host at the decoy IP address, then the SYN-ACK reaches the actual host at the decoy IP address, and not the host running the Nmap scan. Since the real host at the decoy address did not initiate the connection, it closes the connection by sending a TCP Reset (RST). There's no problem with this.

However, a problem occurs if the decoy IP address is not active on the network — there is no RST sent to the scan target, which keeps the connection open. As Nmap continues to generate more and more requests to the target with the decoy IP as the source, the scan target has a growing list of open connections for which it maintains the "connection-initiated" state. This ends up consuming more and more resources on the target and may cause a DoS to other, legitimate hosts and communications.

FIN Scan

The Nmap FIN scan comes in handy in such circumstances. The standard use of a FIN packet is to terminate the TCP connection — typically after the data transfer is complete. Instead of a SYN packet, Nmap initiates a FIN scan by using a FIN packet. Since there is no earlier communication between the scanning host and the target host, the target responds with an RST packet to reset the connection. However, by doing so, it reveals its presence. A FIN scan is initiated using a command like `nmap -sF 192.168.1.1`.

Port Scanning

The second step in reconnaissance is known as port scanning. All networks are secured by one firewall on the perimeter of the network, and this firewall is configured to permit HTTP and SMTP traffic to pass through. Other application traffic is forced to use a secured tunnel to pass through the network. Of course, the perimeter firewall is configured to monitor the traffic, and a log is kept for analysis. Internal network is built using Ethernet segments to reflect the infrastructure of the organization. IP network segments are then superimposed on the Ethernet segments. Each IP network segment is secured from each other by a firewall. Each of the IP segments is connected to the layer-3 switch, thus further protecting each IP segment from an external attack. The IP traffics from the layer-3 switch are directed to pass through a Demilitarized ZONE (DMZ) before it enters the perimeter router. The nodes in the DMZ are DNS, SMTP, and HTTP servers, which are permitted for both inbound and outbound traffic. The attacker would scan the ports on the perimeter firewall and look for open ports on the firewall. The firewall would have the ports such as 80 and 25 (well-known) open for Web and email services. The goal of the attacker is to find which ports in "listen," "wait," or "closed" state.

TCP Full Connect. Full TCP connection is a three-way handshake between a source host and a target host to establish a normal connection. This is used to determine the open TCP ports on the target network, even though the packets have to pass through the firewall. If an intrusion detection system (IDS) is installed on the target

network and configured to trigger an alarm to indicate an anomalous behavior on the network, then this activity will be recorded by IDS.

Ping

This mode sends a short UDP packet to the target's UDP ports and looks for an ICMP "Port Unreachable" message in response. The absence of that message indicates either that the port is in use or the target does not return the ICMP message, which can lead to false positives (A *false positive* occurs when an IDS reports as an intrusion an event that is in fact legitimate network activity). This mode, too, is easily recognized by IDS.

TCP SYN Half Open

In Chapter 27, we talked about the mode of the TCP session. This mode normally sends out a SYN packet to the target port and listens for the appropriate response. Open ports respond with SYN + ACK, and closed ports respond with ACK + RST or RST. This mode is less likely to be recorded by IDS, since the TCP connection is not fully complete, and consequently the attacker might get away with this mode of intrusion.

Fragmentation Scanning

In this method of scanning, you break up IP packets into a number of fragments. Consequently, you are splitting up the TCP header over several packets to make it harder for packet filters and so forth to detect what you are doing. IP fragmentation can also lead to a DoS.

Port Numbers

Public IP addresses are controlled by the Internet Assigned Numbers Authority (IANA) www.iana.org, and are unique globally. Port numbers are unique only within a computer system, and they are 16-bit unsigned numbers. The port numbers are divided into three ranges: the Well Known Ports (0..1023), the Registered Ports (1024..49151), and the Dynamic and/or Private Ports (49152..65535).

Well-Known Ports

Port numbers 0 to 1023 are well-known ports. These well-known ports (also called standard ports) are assigned to services by the IANA. On Unix, the text file named `/etc/services` (on Windows 2000 the file named `%windir%\ system32\ drivers\ etc\ services`) lists these service names and the ports they use. Here are a few lines extracted from this file:

- echo 7/tcp Echo
- ftp-data 20/udp File Transfer [Default Data]
- ftp 21/tcp File Transfer [Control]
- ssh 22/tcp SSH Remote Login Protocol
- telnet 23/tcp Telnet
- domain 53/udp Domain Name Server
- www-http 80/tcp World Wide Web HTTP

Nonstandard Ports

By a nonstandard port, we simply mean a port whose number is higher than 1023. In this range also, several services are "standard." For example:

- wins 1512/tcp # Microsoft Windows Internet Name Service
- yahoo 5010 # Yahoo! Messenger
- x11 6000-6063/tcp # X Window System

Once the IP address of a target system is known, an attacker can then begin the process of port scanning, looking for holes in the system through which the attacker can gain access to the network nodes. We have already discussed the significance of TCP and UDP port numbers, and the well-known and not so well-known services that run at these ports. Each of these ports is a potential entryway or "hole" into the network. If a port is open, there is a service listening on it; well-known services have assigned port numbers, such as http on TCP port 80 or telnet on TCP port 23. Port scanning is the process of sending packets (TCP or UDP) to each port on a system to find out which ones are open.

A port scanner such as Nmap is capable of a wider variety of TCP scans that are harder to detect. Nmap allows an option for a TCP SYN stealth scan in which the third message is not an ACK but a FIN that forces the TCP connection to be closed before fully opening. This half-open connection is not logged at the target, but may be noticed by routers or firewalls that record the original SYN packet.

Nmap also allows options that give the attacker more control over the packets sent. The attacker can set the rate at which packets are sent, since changing the timing to space out the packets can help avoid raising the target's suspicions that it is being scanned. If the rate is set too fast, packets can be lost, and incorrect results will be returned. The attacker can also fragment the packets to avoid intrusion detection systems, many of which only look for the whole suspicious packet to be sent at once. Nmap even allows the attacker to set the source port, for example, to 80 to appear as Web traffic to a packet filter, as well as to set a decoy source address to obscure the real address by sending an extra packet per decoy address.

Bounce Scans

In the bounce scan, the attacker would attempt to fool or mislead the victim into believing that the attack originated from a different source IP address, often known as the distributed denial-of-service attacks (DDoS). Such an attack would make it difficult to trace the attacker's IP address. Most commercial Internet sites such as Yahoo, Google, Microsoft, and others support proxy services so that all Web traffic can be directed to a single server for filtering as well as caching to improve performance. We have seen cases of DDOS in spite of the proxy servers' setup to protect the networks.

Vulnerability Scanning

One essential type of tool for any attacker or defender is the vulnerability scanner. These tools allow the attacker to connect to a target system and check for such vulnerabilities as configuration errors, default configuration settings that allow attackers access, and the most recently reported system vulnerabilities. Most commercial Network Security Services (NSS) are expensive and do not come with the source code, while the open-source NSSs are free and the source code is readily available. The open-source tool Nessus is an extremely powerful network scanner and can be configured to run a variety of attacks. Nessus includes a variety of plug-ins that can be enabled, depending on the type of security checks the user wishes to perform. Nessus includes its own scripting language, called Nessus Attack Scripting Language (NASL), which can be used to create individualized attacks and incorporate them with the other plug-ins. Although attacks could be written in C, Perl, Python, or a variety of other languages, NASL was designed to be an attack language. The screenshot in Figure 28.4 was obtained using a network security scanner from GFI Languard.

3. ENUMERATION

Now we should be ready to generate a laundry list of resources that we identified to be vulnerable using the scanning devices; this is known as Enumeration. Our list would have at a minimum the following resources that we discovered to be vulnerable; DNS, Web, and email servers in the DMZ. If we had managed to penetrate through the firewall, then of course, most of the resources on the Intranet would now be vulnerable to our attacks. We have now completed the Active Reconnaissance, phase one of Figure 28.1.

4. PENETRATION AND GAIN ACCESS

Vulnerable resources on the network have been itemized, so we are ready now to devise an attack scheme and to

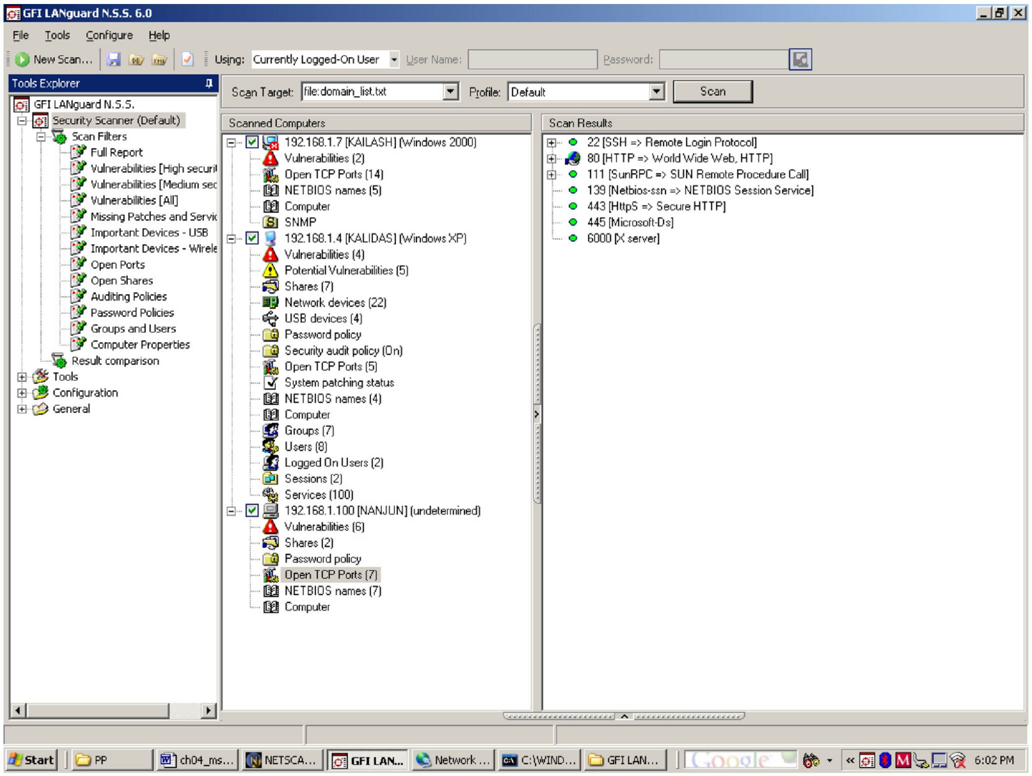

FIGURE 28.4 Vulnerable open ports on the computers in Figure 28.2.

proceed with penetration techniques. Database and HTTP servers are now ready to be compromised.

Stack-Based Buffer Overflow Attacks

Stack-based buffer overflow attacks take advantage of poorly written applications and operating systems architecture. A computer program is a process that is executed by the central processing unit (CPU). Each process manages its memory and input/output. Typically, a process is broken into functions and one main function. This main function is the entry point to the program. Once the program enters the execution mode, the functions in the program get executed as they are called by other functions in a given order. When a called function has completed execution, the control must be returned to the calling function. Herein lay\\ies the problem: When a function is in the execution mode, it needs to store data it is manipulating; this data is stored in a region of memory called a stack. If this region of memory gets overwritten, this will lead to crashing the program—buffer overflow results.

A special-purpose register keeps track of the currently executing instruction, and points to the address of this instruction —Instruction Pointer (IP). This IP is stored on the stack during the function call. Now as you can see, if buffer overflow takes place, then the return addresses get smashed, and the CPU will return to whatever address is available in the IP. The attacker will take advantage of this flow in the architecture by placing the address in the IP.

Once a stack overflow is successful, the returned address gets altered. This altered address is where the attacker will place the payload which could be a virus, a malware, or a Trojan horse. The playload is injected thus, and the attacker will have control of the target network node.

Password Attacks

Every node on a network is secured by assigning a password to access the resources available on the network or on that node. The current policy set by the network administrators is to force the users to change the password over a defined time interval. A new password cannot be a previous password, and it must be alphanumeric and of a certain minimum length to make it difficult for someone to break it. Users' passwords are normally encrypted and stored in a file. If a user forgets the password, then the password will need to be reset as there is no way of recovering the password. An attacker would attempt to get hold of the file that has encrypted passwords. Using password cracking tools as listed below, hacker might be able to recover the plaintext passwords.

Password Cracking Tool: John the Ripper is a password cracker available under Linux and Windows. DoS attacks have become more complicated, concealing malicious client requests as legitimate ones. Also, a distributed approach, the DDoS (distributed denial of service) is now being adopted, which involves generating multiple requests to create a flood scenario. One type of DDoS flood attack is the TCP SYN queue flood.

A SYN queue flood attack takes advantage of the TCP protocol's "three-way handshake." A client sends a TCP SYN (S flag) packet to begin a connection to the server. The target server replies with a TCP SYN-ACK (SA flag) packet, but the client does not respond to the SYN-ACK, leaving the TCP connection "half-open." In normal operations, the client should send an ACK (a flag) packet followed by the data to be transferred, or an RST reply to reset the connection. On the target server, the connection is kept open, in a "SYN_RECV" state, as the ACK packet may have been lost due to network problems.

In a DDoS, multiple attackers make many such half-connections to the target server, in a storm of requests. When the server's SYN buffer is full with half-open TCP connections, it stops accepting SYN connections, thus resulting in denial of service to legitimate clients.

Such DDoS attacks are generally carried out using "botnets" of other compromised systems across the Internet, which through backdoors and Trojans are directed to send artificial SYN flood traffic to targeted servers. To defend against such attacks, a strong monitoring system is required, as there is a very fine line between legitimate and fake clients. SYN queue flood attacks can be mitigated by tuning the kernel's TCP/IP parameters.

Sniffing

The most popular packet sniffer—Wireshark—is a computer program that can monitor the traffic passing over a network or part of a network. Wireshark is normally placed on a network node and configured to run in a promiscuous mode to capture every packet traversing on that network. Sniffer can be configured to capture traffic at any one of the Internet's models, such as layer 2 (Ethernet), layer 3 (IP), layer 3 (TCP or UDP), layer 4 (SMTP, HTTP, DNS, DHCP), or layer 5 (Applications).

Once the data traffic is captured, the hacker would have analyzed the contents of the packets and be able to draw inferences about what is being captured. Hackers would thus have access to port numbers, IP addresses, and application details.

Sniffing Tools

One popular sniffing tool is called Wireshark (http://www.wireshark.com/). The other popular sniffing tool is TCPDump, which can provide very detailed information on the captured data traffic (http://www.tcpdump.org/).

IP Address Spoofing

IP address spoofing normally involves what is known as IP packet crafting. Once again it is a computer program that allows the attacker to target a perimeter router into accepting the IP packet with a disguised IP source address. The real IP source address is spoofed. The purpose of IP spoofing is to make it difficult to trace back to the attacker's node. IP packet crafting is possible by overriding the function of the kernel of the operating system.

MAC Address Modifying Utility: SMAC

Similar to IP address spoofing is a utility that will allow the Ethernet address (MAC) to be spoofed (http://www.klcconsulting.net/smac). The attacker could use nmap to generate packets with the fake IP address in their headers. In this scenario, the target will send any response packets to the spoofed address, so its usefulness is limited to situations where the attacker needs to obscure the source of packets, such as in a denial-of-service attack.

DNS Spoofing

In this case, the domain name system server is spoofed to alter entries of domain names to reflect the attackers' IP address. This results in sending Web or email traffic to the attackers' machine. This attack is achieved by creating multiple forged packets wherein the IP, port, and service type entries are modified to serve the purpose.

Session Hijacking

Session hijacking is an act of taking over an ongoing active connection between two nodes on a network. Hijackers would have been monitoring an active session over a network, using a combination of sniffing and spoofing tools for a while. There is a TCP and UDP session hijacking. The hacker would have to continue to monitor the type of application layer protocol being used between two nodes, since the application layer protocol would decide the type of application being hijacked. We give examples of application layer protocols such as HTTP, SMTP, and DNS used to exchange data between any two active nodes on the network. We remind the reader that all three application layer protocols just stated use the TCP protocol at the layer 3 of the Internet model. Hence the hijacker would have to monitor the TCP port number 80 (HTTP), 25 (SMTP), and 57 (DNS) in order to hijack an active session.

TCP Session Hijacking

Let us recall that a TCP session starts out with a three-way handshake between the two nodes (one node is a client, and the other node is a server) that would like to establish a session between them. The nodes would exchange a sequence of TCP segments with well-defined sequence numbers to establish an active session. This active session is normally terminated by an exchange of FIN (finish) packet or abruptly with RST (reset) packets.

If a would-be hijacker were to correctly guess the sequence number of TCP segments between the two nodes, then it is quite possible that the hijacker could hijack the session before that session gets established between the original TCP client and the server. The original client would still send an ACK segment to the server, but the server would assume that it has received a duplicate segment with a matching sequence number, and thus ignore, as this happens quite a lot of times on the network. This scenario is not a complete description of session hijacking, but just an overview.

Route Table Modification

In this scenario, the attacker would block the packets by modifying the routing tables so that the packets flow through the network that the attacker has the control over. This is known as redirection of traffic and is normally achieved using ICMP (Internet Control Message Protocols) packets.

UDP Hijacking

The DNS protocol would need to be hijacked, if the attacker would want to pretend to be a Web server. The attacker would grab a copy of the HTTP request packet originating from a client to a Web server. Then the attacker would extract the request for a HTTP session from the packet and insert the attacker's IP address, and forward the packet to the client. The client would then establish the HTTP session with the attacker's node, unless the client verified the IP address to confirm that the session has not been hijacked.

Session-Hijacking Tool: Hunt

Hunt (http://packetstormsecurity.org/sniffers/hunt) has sniffing and session hijacking modes. Hunt uses ARP spoofing to establish the attacker's machine as a relay between, say Alice and Bob. When a system prepares to send a packet over a LAN, it first sends out an Address Resolution (ARP) query to all the other systems on the LAN, asking which of them has the Medium Access Control (MAC) address that corresponds to the IP address in the packet's header. The destination system replies with its MAC address, which the source system stores in its ARP cache for a certain period of time. For that period, the source system uses the data from its ARP

cache to send transmissions to that destination. The attacker subverts this process by sending an unsolicited ARP response to Alice that maps Bob's IP address to a fake MAC address, and by sending an unsolicited ARP response to Bob that maps Alice's IP address to a fake MAC address. Both Bob's and Alice's systems overwrite these fake MAC addresses into their ARP caches, so that the packets they send to each other will go to fake addresses. They now cannot send packets to each other for the lifetime of the ARP cache.

Web Hijacking

Hackers may cause serious damage by either defacing the site or using the Web server to spread a virus. Unlike most other attacks, the techniques used in Web attacks range from layer 2 to layer 7 attacks, thus making the Web server susceptible to a wider variety of possible hacking attempts. Since the firewall port must be opened for the Web service (by default, port 80), it cannot help in preventing layer 7 attacks, which makes the detection of Web attacks difficult.

SQL Injection

As we saw earlier, Web portals use database servers in the backend, whereby the Web page connects to the database, queries for data, and presents the fetched data in a Web format to the browser. SQL injection attacks can occur if the input on the client side is not filtered appropriately before it is sent to the database in a query form. This can result in the possibility of manipulating SQL statements in order to perform invalid operations on the database.

A common example for this attack would be that of an SQL server, which is accessed by a Web application, wherein the SQL statements are not filtered by middleware or validation code components. This can lead to the attacker being able to craft and execute his own SQL statements on the backend database server, which could be simple SELECT statements to fetch and steal data, or could be as serious as dropping an entire data table.

5. MAINTAIN ACCESS

All types of service providers on the Internet that hold their clients' sensitive information, are required to notify their clients if a network breach has occurred. This has been mandated by every state in the country. Attackers must remove any evidence of intrusion associated with establishing access, modifying privileges, installing rootkits, and injecting backdoors.

Covering Tracks

Once a network has been compromised, the attacker must make sure that the attacker did not leave footprints behind. Every network runs some sort of security software such as the network intrusion detection system (NDIS), and the intrusion prevention system (IPS). The NDIS detects an intrusion and then reports it so that an appropriate response can be directed to the intrusion.

Backdoors and Trojan Horses

Trojan horses are code disguised as a benign program, but behave in an unexpected manner, usually a malicious manner. Trojan horses are normally injected into a foreign host while that host is browsing the Internet or downloading free utilities from the Internet. The host is normally quite unaware that a malicious program has been injected. This malicious program could hijack future HTTP sessions, monitor the activities on that host, and then relay that information back to the attacker's host and much more. Some noteworthy Trojans are ZeuS, ZeroAccess, TDSS Downloader, Alureon, Gbot, Butterfly bot, and BO2K.

Backdoors and Trojan horses have several things in common. They both come with two pieces of software, the client and the server. The server is the piece that the "remote administrator" will use to infect the victim's computer. The client is the piece that the attacker will use to monitor the victim's computer. Both programs allow for complete access to the victim's files. The hacker can copy, move, rename, delete, and even change any file or folder in the victim's computer.

Backdoor Tool: Netcat

Netcat (http://netcat.sourceforge.net) is a multipurpose networking tool capable of a variety of functions ranging from port scanning and opening connections to remote ports to creating backdoor shells for root access. It runs in either client mode or listening (server) mode.

Rootkits

One way an intruder can maintain access to a compromised system is by installing a rootkit as a Loadable Kernel Module in Linux or as a driver in MS-Windows. Furthermore, rootkits may be injected as user mode, in which case it might be detectable by a virus checker. Kernel-mode rootkits would run with the system privileges by adding a code or replacing portions of the core operating system. Kernel-mode rootkits are difficult to detect and remove, as they have the same level of security as the operating system. A rootkit contains a set of tools

and replacement executables for many of the operating system's critical components, used to hide evidence of the attacker's presence and to give the attacker backdoor access to the system. Rootkits require root access to install, but once they are set up, the attacker can get root access back at any time. A rootkit may also consist of spyware and other programs that monitor traffic and keystrokes and can create a "backdoor" into the system for the hacker to gain access to the hacked node. Third-party software to detect and remove rootkits, Trojans, and Malware can be found at the following URLs:

- http://www.gmer.net
- http://usa.kaspersky.com
- http://www.spamfighter.com

6. DEFEND NETWORK AGAINST UNAUTHORIZED ACCESS

Now that we have completed the discussion on how the hacker might gain control of the target network, we will briefly discuss network perimeter defense (see checklist: An Agenda for Action for Network Security Self-Assessment), known as a firewall, as illustrated in Figure 28.5. Most firewalls are both a hardware and software integrated into one device. The firewall sits on the perimeter that defines the inside of the network from the un-trusted outside. A firewall should provide protection against intruders while allowing trusted users to connect to the network and use the resources therein. To set this scenario, first an access policy has to be defined. This policy is then turned into a set of security rules and is implemented as scripts on the firewall. Hence, firewall rules are defined. Thus, firewalls will examine the packets on the basis of the security policy and will either permit or deny the traffic. The security policy would be made up of a range of IP addresses, port numbers, network protocols (TCP, UDP, IP), and application protocols (HTTP, SMTP, FTP, Telnet). A firewall would have some of the ports open for both authorized inbound and outbound traffic, but the rest of the ports would be closed. Open ports remain a necessary vulnerability; they allow connections to applications, but they may also turn into open doors for attack. In the end, as long as ports remain open, network applications are susceptible to attack. Use of intrusion detection systems (IDS) may certainly help in detecting would-be attackers and thus provide some sense of security.

7. SUMMARY

In this chapter we presented a series of steps undertaken by the intruder to gain unlawful access to networks. The intruder first has to scan the network, thus obtaining the

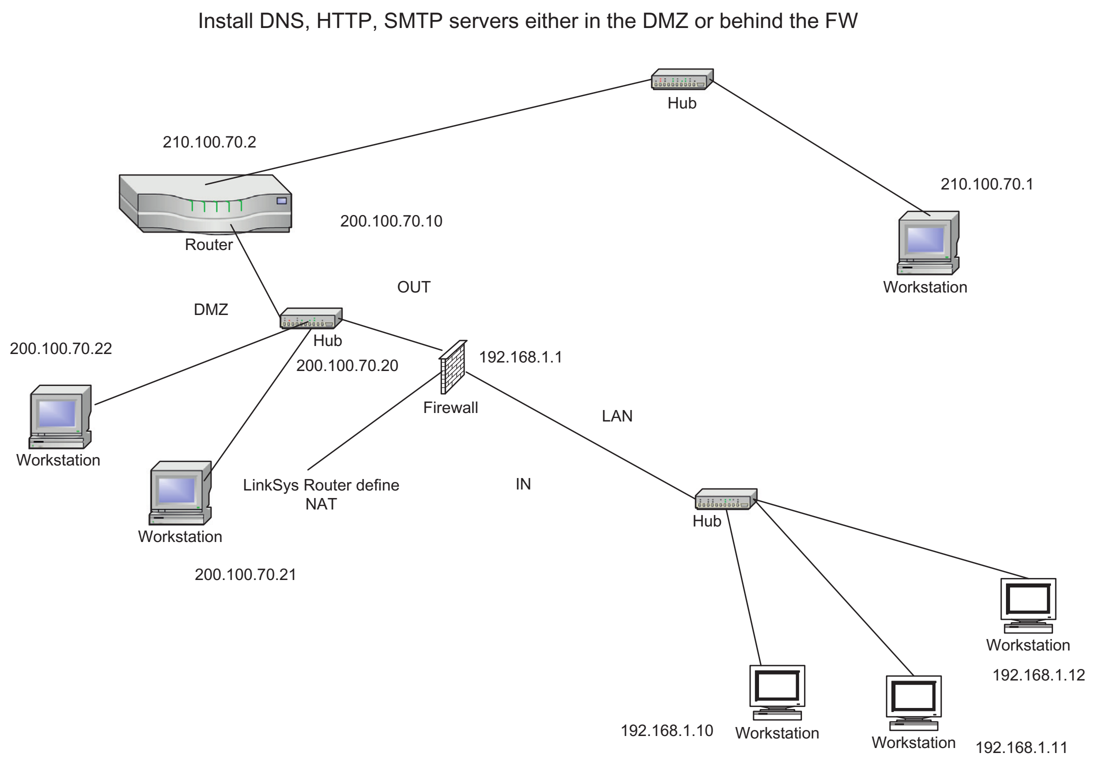

FIGURE 28.5 Network perimeter defense, known as a firewall.

An Agenda for Action for Network Security Self-Assessment

The first step to a self-defending network includes a careful and complete assessment of your network. The Network Security Self-Assessment Checklist shown here can help you quickly assess whether you have network security that is proactive, reactive, or open. The network security practices on this checklist will help ensure that your network is as secure as it can be. It will help you develop proactive, rather than reactive, security and will significantly limit your exposure to threats and the associated liabilities (check all tasks completed).

_____**1.** Conducting network and endpoint security assessments.
_____**2.** Classifying all network and information assets.
_____**3.** Deploying integrated security solutions with intelligent self-defending capabilities.
_____**4.** Identifying areas of regulatory similarities to minimize overhead and avoid duplicate investments in network security. For example, GLBA, the USA Patriot Act, and SOX all require consideration of capabilities for:
  _____**a.** Firewalls
  _____**b.** Encryption
  _____**c.** Access Controls
  _____**d.** Virtual Private Networks
  _____**e.** Intrusion Detection and Prevention
  _____**f.** Anti-virus Software
  _____**g.** Monitoring, Auditing, and Reporting
_____**5.** Aligning your people, processes, and technology to protect your institution.
_____**6.** Educating each employee on his or her security duties and responsibilities.
_____**7.** Managing security as an essential, dynamic, and ongoing project.
_____**8.** Regularly testing your network and endpoint security to identify weaknesses.
_____**9.** Responding immediately and appropriately to known and unknown or emerging security threats.
_____**10.** Updating your security practices to comply with new laws, rules, and guidelines and protect against new threats.
_____**11.** Identifying and reporting security-related events to executive management and the board of directors.

information regarding the resources available on the network. Once the intruder has completed the profile of the network and identified the "holes" in the network, he or she is ready to launch the attack. Next, the intruder would attempt to gain access to the network with the tools that are freely accessible on the Internet. If the intruder is successful in hacking into the network, then he or she could establish a backdoor entrance to the network. In later chapters we will introduce the topic of how network penetration can be achieved, with the tools that are freely available on the Internet. The reader should be warned that network intrusion is a punishable offense.

Now, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Network mapping is the process of discovering information about the topology of the target network, thus finding the IP addresses of gateways, routers, email, Web, FTP servers, and database servers.
2. True or False? The Nmap main page is described as an exploration tool and port-scanner.
3. True or False? Zombie hosts are those controlled by others on the network.
4. True or False? The decoy host command is not especially useful while testing IDS/IPS.
5. True or False? The standard use of a FIN packet is to not terminate the TCP connection — typically after the data transfer is complete.

Multiple Choice

1. Discover network interconnection and configuration, and look for network vulnerabilities:
   A. DOS
   B. Sniffing
   C. SYN flooding
   D. Reconnaissance
   E. All of the above
2. Removal and/or alteration of data, installing "backdoors," and hiding the tracks of attack activities is known as
   A. enumeration
   B. scanning
   C. DoS
   D. operational attacks
   E. all of the above
3. The port scanning technique is used to discover open _______ ports.
   A. TCP
   B. NetBIOS

C. PDP
D. HTTP
E. All of the above

4. The three-way TCP handshake is established during which of the TCP scanning sessions?
   A. TCP connect()
   B. TCP SYN
   C. TCP FIN
   D. TCP Open
   E. All of the above
5. TCP SYN scanning is also known as
   A. full open
   B. half open
   C. full close
   D. half close
   E. All of the above

EXERCISE

Problem

Download IP-tools and install the software:

1. Visit the Web site, http://www.ks-soft.net.
2. Download the software "IP-Tools."
3. Install IP-tools on your computer.

Hands-On Projects

Project

Download LANguard N.S.S. (Commercial grade Network Security Scanner, N.S.S.):

1. Visit the Web site, http://www.gfi.com.
2. Download LANguard N.S.S., a trial version.
3. Install the software on your computer.
4. Under Tools Explorer, select Whois.
5. Enter the Internet domain such as cox.net to discover the name servers and the IP addresses of the cox.net domain.

Case Projects

Problem

Using LANguard software to rnumerate the computers in your Windows domain:

1. Open LANguard application.
2. Under Tools Explorer, select Tools, and then Enumerate Computers.
3. Enter the domain in which you wish to enumerate.
4. Click the Retrieve TAB.
5. Copy the list of the computers thus displayed.

Optional Team Case Project

Problem

In this case study, you are to learn about RAW Sockets and to compare them with standard TCP/IP or Winsocks. This should prepare you to understand how TCP/IP packets are normally generated by the kernel, and to learn how a hacker bypassed the kernel to inject custom packets to attack a network.

Firewalls

Dr. Errin W. Fulp
Wake Forest University

1. INTRODUCTION

Providing a secure computing environment continues to be an important and challenging goal of any computer administrator. The difficulty is in part due to the increasing interconnectivity of computers via networks, which includes the Internet. Such interconnectivity brings great economies of scale in terms of resources, services, and knowledge, but it has also introduced new security risks. For example, interconnectivity gives illegitimate users much easier access to vital data and resources from almost anywhere in the world.

In a secure environment it is important to maintain the privacy, integrity, and availability of data and resources. *Privacy* refers to limiting information access and disclosures to authorized users and preventing access by or disclosure to illegitimate users. In the United States, a range of state and federal laws—for example, FERPA, FSMA, and HIPAA—define the legal terms of privacy. *Integrity* is the trustworthiness of information. It includes the idea of *data integrity*, which means data has not been changed inappropriately. It can also include *source integrity*, which means the source of the data is who it claims to be. *Availability* is the accessibility of resources. Of course these security definitions can also form the basis of *reputation*, which is vital to businesses.

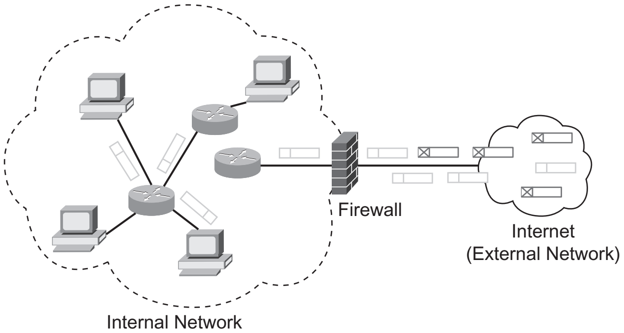

FIGURE e29.1 Example network consisting of an internal network (which is to be secured) and an external network (not trusted). The firewall controls access between these two networks, allowing and denying packets according to a security policy.

2. NETWORK FIREWALLS

Network firewalls (see checklist: "An Agenda For Action For Network Firewalls") are a vital component for maintaining a secure environment and are often the first line of defense against attack. Simply stated, a firewall is responsible for controlling access among devices, such as computers, networks, and servers. Therefore the most common deployment is between a secure and an insecure network (for example, between the computers you control and the Internet), as shown in Figure e29.1.

However, in response to the richer services provided over modern networks (such as multimedia and encrypted connections), the role of the firewall has grown over time. Advanced firewalls may also perform Network Address Translation (NAT), which allows multiple computers to share a limited number of network addresses (explained later in this chapter). Firewalls may provide service differentiation, giving certain traffic priority to ensure that data is received in a timely fashion. Voice over IP (VoIP) is one type of application that needs differentiation to ensure proper operation. This idea is discussed several times in this chapter, since the use of multimedia services will only continue to increase. Assuming that email and VoIP packets arrive at the firewall at the same time, VoIP packets should be processed first because the application is more susceptible to delays.

Firewalls may also inspect the contents (the data) of packets. This can be done to filter other packets (learn new connections), block packets that contain offensive information, and/or block intrusion attempts. Using the mail analogy again, in this case you open letters and determine what to accept based on what is inside. For example, you unfortunately have to accept bills, but you can deny credit-card solicitations.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00029-5

An Agenda for Action for Network Firewalls

The following checklist lists the major tasks for network firewalls (check all tasks completed):

_____**1.** The use of network address translation (NAT) should be considered a form of routing, not a type of firewall.

_____**2.** Organizations should only permit outbound traffic that uses the source IP addresses in use by the organization.

_____**3.** Compliance checking is only useful in a firewall when it can block communication that can be harmful to protected systems.

_____**4.** When choosing the type of firewall to deploy, it is important to decide whether the firewall needs to act as an application proxy.

_____**5.** Management of personal firewalls should be centralized to help efficiently create, distribute, and enforce policies for all users and groups.

_____**6.** In general, a firewall should fit into a current network's layout. However, an organization might change its network architecture at the same time as it deploys a firewall as part of an overall security upgrade.

_____**7.** Different common network architectures lead to very different choices for where to place a firewall, so an organization should assess which architecture works best for its security goals.

_____**8.** If an edge firewall has a DMZ, consider which outward-facing services should be run from the DMZ and which should remain on the inside network.

_____**9.** Do not rely on NATs to provide the benefits of firewalls.

_____**10.** In some environments, putting one firewall behind another may lead to a desired security goal, but in general such multiple layers of firewalls can be troublesome.

_____**11.** An organization's firewall policy should be based on a comprehensive risk analysis.

_____**12.** Firewall policies should be based on blocking all inbound and outbound traffic, with exceptions made for desired traffic.

_____**13.** Policies should take into account the source and destination of the traffic in addition to the content.

_____**14.** Many types of IPv4 traffic, such as that with invalid or private addresses, should be blocked by default.

_____**15.** Organizations should have policies for handling incoming and outgoing IPv6 traffic.

_____**16.** An organization should determine which applications may send traffic into or out of its network and make firewall policies to block traffic for other applications.

3. FIREWALL SECURITY POLICIES

When a packet arrives at a firewall, a security policy is applied to determine the appropriate action. Actions include accepting the packet, which means the packet is allowed to travel to the intended destination. A packet can be denied, which means the packet is not permitted to travel to the intended destination (it is dropped or possibly is bounced back). The firewall may also log information about the packet, which is important to maintain certain services.

It is easy to consider a firewall policy as an ordered list of rules, as shown in Table e29.1. Each firewall rule consists of a set of tuples and an action. Each tuple corresponds to a field in the packet header, and there are five such fields for an Internet packet: Protocol, Source Address, Source Port, Destination Address, and Destination Port.

The firewall rule tuples can be fully specified or contain wildcards (*) in standard prefix format. However, each tuple represents a finite set of values; therefore, the set of all possible packets is also finite. (A more concise mathematical model will be introduced later in the chapter.) It is possible to consider the packet header consisting of tuples, but each tuple must be fully specified.

As packets pass through a firewall, their header information is sequentially compared to the fields of a rule. If a packet's header information is a subset of a rule, it is said to be a match, and the associated action, to accept or reject, is performed. Otherwise, the packet is compared to the next sequential rule. This is considered a *first-match policy* since the action associated with the first rule that is matched is performed. Other matching strategies are discussed at the end of this section.

For example, assume that a packet has the following values in the header: The protocol is TCP, source IP is 210.1.1.1, source port is 3080, destination IP is 220.2.33.8, and destination port is 80. When the packet arrives it is compared to the first rule, which results in no match since the rule is for UDP packets. The firewall then compares the packet second rule, which results in no match since the source IP is different. The packet does not match the third rule, but it does match the fourth rule. The rule action is performed and so the packet is allowed to pass the firewall.

A default rule, or catch-all, is often placed at the end of a policy with action reject. The addition of a default rule makes a policy comprehensive, indicating that every packet will match at least one rule. In the event that a

TABLE e29.1 A Security Policy Consisting of Six Rules, Each of Which Has Five Parts (Tuples).

No.	Protocol	Source		Destination		Action
		IP	Port	IP	Port	
1	UDP	190.1.1.*	*	*	80	deny
2	TCP	180.*	*	180.*	90	accept
3	UDP	210.1.*	*	*	90	accept
4	TCP	210.*	*	220.*	80	accept
5	UDP	190.*	*	*	80	accept
6	*	*	*	*	*	deny

packet matches multiple rules, the action of the first matching rule is taken. Therefore the order of rules is very important.

If a default rule (a rule that matches all possible packets) is placed at the beginning of a first-match policy, no other rule will match. This situation is an anomaly referred to as *shadowing*. We'll talk more about policy anomalies later in this chapter. Policies that employ this form of short-circuit evaluation are called *first-match policies* and account for the majority of firewall implementations.

Rule-Match Policies

Multiple rules of a single firewall policy may match a packet—for example, a packet could match rules 1, 5, and 6 of the policy in Table 29.1. Given multiple possible matches, the rule-match policy describes the rule the firewall will apply to the packet. The previous section described the most popular match policy, first match, which will apply the first rule that is a match.

Other match policies are possible, including best match and last match. For best-match policies, the packet is compared against every rule to determine which rule most closely matches every tuple of the packet. Note that the relative order of the rules in the policy does not impact determining the best-match result; therefore shadowing is not an issue. It is interesting to note that best match is the default criterion for IP routing, which is not surprising since firewalls and routers do perform similar tasks. If a packet matches multiple rules with a last-match criterion, the action of the last rule matched is performed. Note that rule order is important for a last-match policy.

4. A SIMPLE MATHEMATICAL MODEL FOR POLICIES, RULES, AND PACKETS

At this point it is perhaps useful to describe firewall policies, firewall rules, and network packets using set theory.[1] The previous section defined the parts and fields of rules and packets as *tuples*. A tuple can be modeled as a set. For example, assume the tuple for IP source addresses is 198.188.150.*. Then this tuple represents the set of 256 addresses that range from 198.188.150.0 to 198.180.150.255. Each tuple of a packet consists of a single value, which is expected, since a packet only has one source and one destination.

The tuples (which are sets) that form a rule collective define a set of packets that match. For example, consider the following rule:

- Proto = TCP, SIP = 190.150.140.38, SP = 188,
- DIP = 190.180.39.* DP = 80, action = accept

This rule defines a set of 256 unique TCP packet headers with source address 190.150.140.38 and source port 188 destined for any of the 256 computers with destination port 80 and destination IP address 190.180.39.0 through 190.180.39.255, perhaps a Web server farm. Therefore the rule describes a set of 256 packets that will be accepted. If the source port was defined as *, the rule would describe a set of 16,777,216 different packet headers.

$$2^{16} \times 2^{8} = 65,536 \times 256 = 16,777,216$$

1. Errin W. Fulp, "Optimization of network firewall policies using directed acyclical graphs," In *Proceedings of the IEEE Internet Management Conference*, 2005.

Using set theory also provides a simple definition of a match. A match occurs when every tuple of a packet is a proper subset of the corresponding rule. In this chapter a proper set can be thought of as one set completely contained within another. For example, every tuple in the following packet is a proper subset of the preceding rule; therefore it is considered a match:

- Proto = TCP, SIP = 190.150.140.38, SP = 188,
- DIP = 190.180.39.188 DP = 80

A set model can also be used to describe a firewall policy. The list of rules in a firewall policy collectively describes a set of packets. There are three distinct (nonoverlapping) sets of possible packets. The first set, *A(R)*, describes packets that will be accepted by the policy *R*. The second set, *D(R)*, defines the set of packets that will be dropped by the policy. The last set, *U(R)*, is the set of packets that do not match any rule in the policy. Since the sets do not overlap, the intersection of *A(R), D(R)*, and *U(R)* should be the empty set.

Using set theory we can also define the set *P* that describes all possible packet headers, of which there are approximately 7.7×10^{25} possible packet headers. A packet is a single element in this large set.

Using accept, drop, nonmatch, and possible packet sets, we can describe useful attributes of a firewall policy. A firewall policy *R* is considered comprehensive if any packet from *P* will match at least one rule. In other words, the union of *A(R)* and *D(R)* equals *P* (therefore *A(R)D (R)* = *P)*, or *U(R)* is the empty set (therefore *U(R)* = Ø). Of course, it is better if a policy is comprehensive, and generally the last rule (catch-all) makes this true.

Finally, these mathematical models also allow the comparison of policies, the most important reason for introducing a somewhat painful section. Assume two firewall policies *R* and *S* exist. We can say the two polices are equivalent if the accept, drop, and nonmatch sets are the same. This does not imply that the two policies have the same rules, just that given a packet, both policies will have the same action. This is an important property that will be mentioned again and again in this chapter.

5. FIRST-MATCH FIREWALL POLICY ANOMALIES

As described in the previous sections, for most firewalls the first rule that matches a packet is typically applied. Given this match policy, more specific rules (those that match few packets) typically appear near the beginning of the policy, whereas more general rules are located at the end. Using the set theory model, the number of elements in the rules sets increases as you move toward the last rule.

Unfortunately, it is easy to introduce anomalies when developing and managing a firewall policy. This is especially true as the policy grows in size (number of rules) and complexity. An anomaly is an unintended consequence of adding rules in a certain order.

A simple and very common anomaly is rule shadowing. Shadowing occurs when an earlier rule r_i matches every packet that another lower rule r_j matches, where i and j are rule numbers. Assume rules are numbered sequentially starting at the first rule and $i < j$. Using the mathematical model, shadowing occurs when every tuple in r_j is a proper subset of r_i

For example, shadowing occurs between the following two rules:

- Proto = TCP, SIP = 190.150.140.38, SP = 188,
- DIP = 190.180.39.* DP = 80, action = accept
- Proto = TCP, SIP = 190.150.140.38, SP = 188, DIP = 190.180.39.180 DP = 80, action = drop

What is the problem? Nothing, if the two rules have the same action (there is a performance issue described in the next section). However, if the rules have different actions, there is a potential issue. In the preceding example the second rule is never matched; therefore the packet [Proto = TCP, SIP = 190.150.140.38, SP = 188, DIP = 190.180.39.180 DP = 80] will always be accepted. Was this the intent? If so, the second rule should be removed.

Another policy anomaly is half shadowing, where only a portion of the packets of a later rule matches an earlier rule (although not necessarily half of the packets in the set). For example, consider the following two rules:

- Proto = TCP, SIP = 190.150.140.38, SP = 188,
- DIP = 190.180.39.* DP = 80, action = accept
- Proto = TCP, SIP = 190.150.140.38, SP = *,
- DIP = 190.180.39.180 DP = 80, action = drop

In this example, the second rule is partially shadowed by the first rule. By itself, the second rule will drop any TCP packet arriving from the address 190.150.140.38 and destined for the Web server (because of destination port 80) 190.180.39.180. When the first rule is added, a packet from the address 190.150.140.38 and port 188 will be accepted. Was this the intent? Only the firewall administrator would know. Regardless, it is difficult to detect.

Other firewall policy anomalies are possible. Unfortunately, detecting these problems is not easy, since the anomaly may be introduced on purpose (then technically it is not an anomaly). This has created a new area of research, and some software packages are available to help find problems. However, only the administrator can ultimately determine whether the rule ordering is correct. Note that best-match policies do not have these

issues, and this reason is often used to promote their use. However, best-match policies are typically considered difficult for the administrator to manage.

6. POLICY OPTIMIZATION

Given that a network firewall will inspect all packets transmitted between multiple networks, these devices need to determine the appropriate match with minimal delay. Often the number of firewall rules in a policy will impact the firewall performance. Given that every rule requires some processing time, more rules will require more time, on average. There are a few ways to improve firewall performance with regard to the security policy. Note that this section is more applicable to software-based than hardware-based firewalls.

Policy Reordering

Given a security policy, it may be possible to reorder the rules such that more popular rules appear earlier.[2] *More popular* refers to how often the rule is a match. For example, over time it is possible to determine how many times a rule is matched. Dividing this number by the total number of packets matched for the entire policy yields the probability that this rule is considered the first match.

If the match policy is first match, then placing more popular rules earlier in the policy will reduce the average number of rule comparisons. The average number of rule comparisons performed, *E[n]*, is given by the following equation:

$$E[n] = \sum_{i=1}^{n} i \times p_i$$

where n is the number of rules in the policy and p_i is the probability that rule i is the first match. Although reordering is advantageous, it must be done so that the policy's integrity is maintained.

Policy integrity refers to the policy intent, so the policy will accept and deny the same packets before and after the reorganization of rules. For example, rule six in Table 29.1 may be the most popular rule (the default deny), but placing it at the beginning of the policy does not maintain integrity. However, if rule two is more popular than rule one, it could be placed at the beginning of the policy and integrity will be maintained. Therefore the order between certain rules must be maintained.

This can be described mathematically using the models introduced in the earlier section. Assume a firewall policy R exists. After reordering the rules, let's call the firewall policy S. If $A(R) = A(S)$ and $D(R) = D(S)$, then the policies R and S are equivalent and integrity is maintained. As a result S can be used in place of R in the firewall, which should improve performance.

Although a simple concept, reordering rules to maintain integrity is provably difficult for large policies.[3,4] Fortunately, commercial software packages are now available to optimize rules to improve performance.

Combining Rules

Another method for improving firewall performance is removing unnecessary rules. This can be accomplished by first removing redundant rules (rules that are shadowed with the same action). For example, the second rule here is unnecessary:

- Proto = TCP, SIP = 190.150.140.38, SP = 188,
- DIP = 190.180.39.* DP = 80, action = drop
- Proto = TCP, SIP = 190.150.140.38, SP = 188,
- DIP = 190.180.39.180 DP = 80, action = drop

This is because the first rule matches any packet the second rule does, and the first rule has the same action (different actions would be an anomaly, as described in the earlier sections).

Another example occurs when two nonshadowing rules can be combined into a single rule. Consider the following two rules:

- Proto = TCP, SIP = 190.150.140.38, SP = 188,
- DIP = 190.180.39.* DP = 80, action = accept
- Proto = UDP, SIP = 190.150.140.38, SP = 188,
- DIP = 190.180.39.* DP = 80, action = accept

These two rules can be combined into the following rule, which substitutes the wildcard for the protocol field:

- Proto = *, SIP = 190.150.140.38, SP = 188,
- DIP = 190.180.39.* DP = 80, action = accept

Combining rules to form a smaller policy is better in terms of performance as well as management in most cases, since fewer rules should be easier for the administrator to understand. Finding such combinations takes practice; fortunately, there are some software packages available to help.

Default Accept or Deny?

It may be worth a few lines to discuss whether a default accept policy provides better performance than a default

2. Errin W. Fulp, "Optimization of network firewall policies using directed acyclical graphs," In *Proceedings of the IEEE Internet Management Conference*, 2005.

3. Errin W. Fulp, "Optimization of network firewall policies using directed acyclical graphs," In *Proceedings of the IEEE Internet Management Conference*, 2005.

4. M. Yoon and Z. S. Zhang, "Reducing the size of rule set in a firewall," In *Proceedings of the IEEE International Conference on Communications*, 2007.

deny. This debate occurs from time to time; generally speaking, the question is better answered with regard to management of the policy and security. Is it easier to define the appropriate policy in terms of what is denied or what should be accepted?

Assuming that the administrator defines one (accepted or denied), the default behavior becomes the other. A "define what is accepted and default deny" is the most common. It can be considered pessimistic, since it assumes that if you are not certain about a packet, then drop it.

7. FIREWALL TYPES

Firewalls can be categorized into three general classes: packet filters, stateful firewalls, and application layer firewalls.[5] Each type provides a certain type of security and is best described within the context of a network layer model—for example, the Open Systems Interconnect (OSI) or TCP/IP model, as shown in Figure e29.2.

Recall that the TCP/IP model consists of four basic layers: data link, networking (IP), transport (TCP and UDP), and application. Each layer is responsible for providing a certain service to the layer above it. The first layer (data link) is responsible for transmitting information across the local area network (LAN); examples include Ethernet and 802.11 networks. The network layer (routing, implemented IP) concerns routing information across interconnected LANs. The third layer (transport, implemented as TCP and UDP) concerns the end-to-end connection between communicating devices. The highest layer (application) is the application using the network.

Packet Filter

A packet filter is the most basic type of a firewall since it only filters at the network and transport layers (layers two

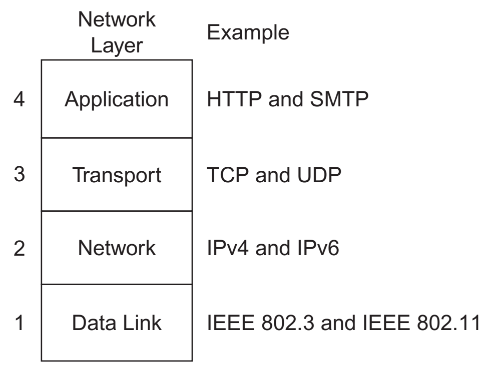

FIGURE e29.2 Layered model for computer networks and example implementations for each layer.

5. J.R. Vacca and S. R. Ellis, *Firewalls Jumpstart for Network and Systems Administrators*, Elsevier, 2005.

and three). Therefore a packet filter's operations are similar to a network router's. The packet filter receives a packet, determines the appropriate action based on the policy, then performs the action on the packet. This will be based on the information from the network and transport layers. Therefore, a packet filter only considers the IP addresses (layer two information), the port numbers (layer one information), and the transport protocol type (layer three information). Furthermore, since all this information resides in the packet header, there is no need to inspect the packet data (payload). It is possible to filter based on the data link layer, but this chapter only considers the network layer and above. Another important note is that the packet filter has no memory (or state) regarding the packets that have arrived and departed.

Stateful Packet Firewalls

Stateful firewalls perform the same operations as packet filters but also maintain state about the packets that have arrived. Given this additional functionality, it is now possible to create firewall rules that allow network sessions (sender and receiver are allowed to communicate), which is critical given the client/server nature of most communications (that is, if you send packets, you probably expect something back). Also note the change in terminology from packet filter to firewall. Many people say that when state is added to a packet filter, it becomes a firewall. This is really a matter of opinion.

For example, assume a user located in the internal (protected) network wants to contact a Web server located in the Internet. The request would be sent from the user to the Web server, and the Web server would respond with the requested information. A packet filter would require two rules, one allowing departing packets (user to Web server) and another allowing arriving packets (Web server to user). There are several problems with this approach, since it is difficult to determine in advance what Web servers a user will connect to. Consider having to add a new rule for every Web server that is or would ever be contacted.

A stateful firewall allows connection tracking, which can allow the arriving packets associated with an accepted departing connection. Recall that a connection or session can be considered all the packets belonging to the conversation between computers, both sender to receiver, and vice versa. Using the Web server example, a single stateful rule can be created that accepts any Web requests from the secure network and the associated return packets. A simple way to add this capability is to have the firewall add to the policy a new rule allowing return packets. Of course, this new rule would be eliminated once the connection is finished. Knowing when a connection is finished is not an easy task, and ultimately timers

are involved. Regardless, stateful rules were a significant advancement for network firewalls.

Application Layer Firewalls

Application layer firewalls can filter traffic at the network, transport, and application layer. Filtering at the application layer also introduces new services, such as proxies. Application proxies are simply intermediaries for network connections. Assume that a user in the internal network wants to connect to a server in the external network. The connection of the user would terminate at the firewall; the firewall would then create a connection to the Web server. It is important to note that this occurs seamlessly to the user and server.

As a result of the proxy the firewall can potentially inspect the contents of the packets, which is similar to an intrusion detection system (IDS). This is increasingly important since a growing number of applications, as well as illegitimate users, are using nonstandard port numbers to transmit data. Application layer firewalls are also necessary if an existing connection may require the establishment of another connection—for example, the Common Object Resource Broker Architecture (CORBA).

Increasingly, firewalls and other security devices are being merged into a single device that can simplify management. For example, an intrusion prevention system (IPS) is a combination firewall and IDS. An IPS can filter packets based on the header, but it can also scan the packet contents (payload) for viruses, spam, and certain types of attacks.

8. HOST AND NETWORK FIREWALLS

Firewalls can also be categorized based on where they are implemented or what they are intended to protect—host or network.[6] Host firewalls typically protect only one computer. Host firewalls reside on the computer they are intended to protect and are implemented in software (this is described in the next section).

In contrast, network firewalls are typically standalone devices. Located at the gateway(s) of a network (for example, the point at which a network is connected to the Internet), a network firewall is designed to protect all the computers in the internal network. As a result, a network firewall must be able to handle high bandwidth, as fast as the incoming connection, and process packets quickly. A network firewall gives administrators a single point at which to implement and manage security, but it is also a single point of failure.

There are many different network configurations that involve firewalls. Each provides different levels of security and management complexity. These configurations are described in detail in a later section.

9. SOFTWARE AND HARDWARE FIREWALL IMPLEMENTATIONS

As described in the previous sections, a firewall applies a policy to an arriving packet to determine the appropriate match. The policy is an ordered list of rules, and typically the first rule that matches the packet is performed. This operation can be performed primarily in either software or hardware. Performance is the principal reason to choose one implementation.

Software firewalls are application software that can execute on commercial hardware. Most operating systems provide a firewall to protect the host computer (often called a *host firewall)*. For example, iptables is the firewall application provided as a part of the Linux operating system. Several major firewall companies offer a software version of their network firewall. It is possible to buy off-the-shelf hardware (for example, a server) and run the firewall software. The advantage of software firewalls is their ability to upgrade without replacing the hardware. In addition, it is easier to add new features—for example, iptables can easily perform stateful filtering, NATing, and quality-of-service (QoS) operations. It is as simple as updating and configuring the firewall software.

Hardware firewalls rely on hardware to perform packet filtering. The policy and matching operation is performed in dedicated hardware—for example, using a field-programmable gate array (FPGA). The major advantages of a hardware firewall are increased bandwidth and reduced latency. Note that bandwidth is the number of packets a firewall can process per unit of time, and latency is the amount of time require to process a packet. They are not the same thing, and IETF RFC 3511 provides a detailed description of the process of testing firewall performance.[7]

Hardware firewalls can operate at faster bandwidths, which translates to more packets per second (10 Gbps is easily achieved). In addition, hardware firewalls can operate faster since processing is performed in dedicated hardware. The firewall operates almost at wireline speeds; therefore, very little delay is added to accepted packets. This is important since more applications, such as multimedia, need QoS for their operation. The disadvantage is that upgrading the firewall may require replacement of hardware, which can be more expensive.

7. B. Hickman, D. Newman, S. Tadjudin, and T. Martin, *Benchmarking Methodology for Firewall Performance*, IETF RFC 3511, 2003.

10. CHOOSING THE CORRECT FIREWALL

The previous sections have described several categories of firewalls. Firewalls can be packet filters or stateful firewalls and/or provide application layer processing; implemented at the host or network or implemented in software or hardware. Given the possible combinations, it can be difficult to choose the appropriate technology.

When determining the appropriate technology, it is important to first understand the current and future security needs of the computer system being protected. Given a large number of hosts, a network firewall is probably the easiest to manage. Requiring and relying on every computer in an internal network to operate a host firewall may not be realistic.

Furthermore, updating the policy in a multiple host-based firewall system would be difficult. However, a single network firewall may imply that a single policy is suitable for all computers in the internal network. This generally is not the case when there are servers and computers in the internal network. More expensive network firewalls will allow the implementation of multiple policies or objects (described in more detail in the next section). Of course, if speed is an issue, a hardware firewall may justify the generally higher cost.

If scanning for viruses and spam and/or discovering network attacks are also requirements, a more advanced firewall is needed. Sometimes called an intrusion prevention system (IPS), these advanced devices filter based on packet headers and inspect the data transmitted for certain signatures. In addition, these devices can monitor traffic (usage and connection patterns) for attacks. For example, a computer that attempts to connect to a range of ports on another computer is probably *port scanning*. This can be done to determine what network-oriented programs are running and in some cases even the operating system can be determined. It is a good idea to block this type of network reconnaissance, which an advanced firewall can do.

Although already introduced in this chapter, it is worth mentioning IETF RFC 3511 again. This document describes how firewalls should be tested to measure performance. This information helps the buyer understand the performance numbers cited by manufacturers. It is also important to ask whether the device was tested under RFC 3511 conditions.

11. FIREWALL PLACEMENT AND NETWORK TOPOLOGY

A simple firewall typically separates two networks: one trusted (internal—for example, the corporate network) and one untrusted (external—for example, the Internet). In this simple arrangement, one security policy is applied to secure all the devices connected to the internal network. This may be sufficient if all the computers perform the same duties, such as desktop computers; however, if the internal network consists of different types of computers (in terms of the services provided), a single policy or level of protection is not sufficient or is difficult to create and maintain.

For example, the security policy for a Web server will be different from the security policy for a desktop computer. This is primarily due to the type of external network access each type of computer needs. Web servers would probably accept almost any unsolicited HTTP (port 80) requests arriving from the Internet. However, desktop computers probably do not serve Web pages and should not be subject to such requests.

Therefore it is reasonable to expect that different classes of computers will need different security policies. Assume an internal network consists of one Web server and several desktop computers. It is possible to locate the Web server on the outside, on the firewall (on the side of the external network), but that would leave the Web server without any firewall protection. Furthermore, given that the Web server is on the outside, should the administrator trust it?

Of course, the Web server could be located in the internal network (see Figure e29.3) and a rule can be added to the policy to allow Web traffic to the Web server (often called *poking a hole)*. However, if the Web server is compromised, the remaining computers in the internal network are vulnerable. Most attacks are multistage, which means the first target of attack is rarely the objective. Most attackers use one computer to compromise another until the objective is achieved. Therefore it is a good practice to separate machines and services, even in the internal network.

Demilitarized Zones

Another strategy often employed to provide different types of protection is a *demilitarized zone* (DMZ), as shown in Figure 29.3. Assume the firewall has three connections (sometimes called a *multihomed* device)—one for the external network (Internet), one for the Web server, and another for the internal network. For each connection to the firewall (referred to as an *interface*), a different firewall policy can be enforced, providing different forms of protection. The connection for the Web server is called the DMZ, and it prevents users from the external network getting direct access to the other computers in the internal network. Furthermore, if the Web server is compromised, the internal network still has some protection, since the intruder would have to cross the firewall again to access the internal network.

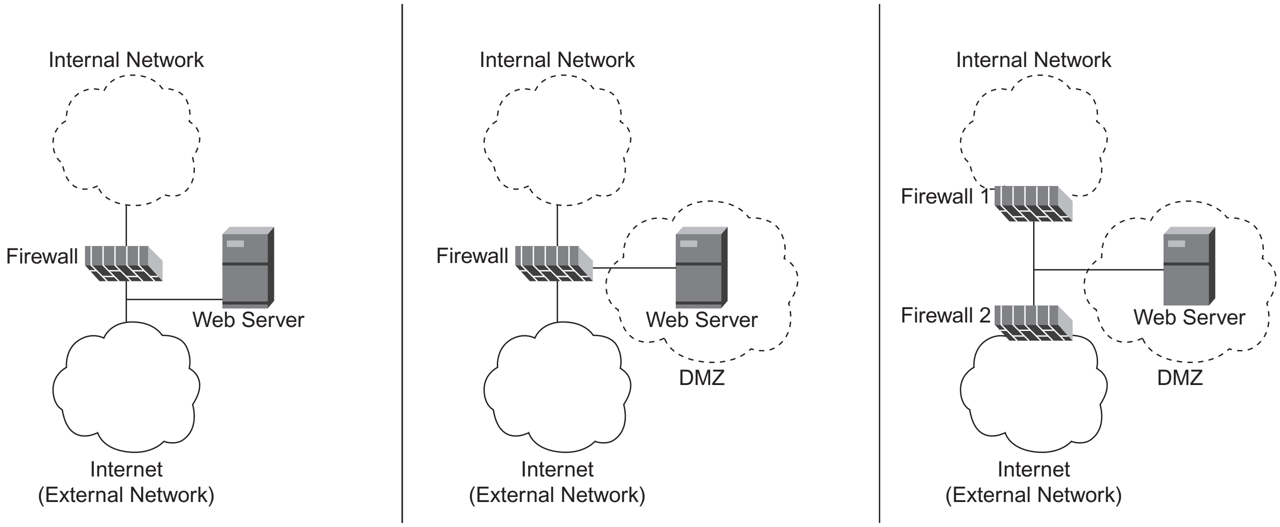

FIGURE e29.3 Example firewall configurations. Left configuration has a Web server outside the internal network. The middle configuration has the Web server in a demilitarized zone. The right configuration is another example of a demilitarized zone.

If the firewall only supports two interfaces (or just one policy), multiple firewalls can be used to achieve the same DMZ effect. The first firewall would be placed between the external network and the Web server. The second firewall would connect the Web server to the internal network. Given this design, the first firewall policy would be less restrictive than the second. Again, different levels of security are now possible.

Grouping machines together based on similar firewall security needs is increasingly common and is seen as a good practice. Large networks may have server farms or a group of servers that perform similar services. As such, each farm is connected to a firewall and given a unique security policy. For example, users from the internal network may have access to administrative servers, but Web servers may have no access to the administrative servers. Such groupings are also referred to as *enclaves*.

Perimeter Networks

A perimeter network is a subnetwork of computers located outside the internal network.[8] Given this definition, a DMZ can be considered a type of perimeter network. The primary difference between a DMZ and a perimeter network is the way packets arriving and departing the subnetwork are managed.

In a perimeter network, the device that connects the external network to the perimeter network is a *router*, whereas a DMZ uses a firewall to connect to the Internet. For a DMZ, a firewall policy will be applied to all packets arriving from the external network (Internet). The firewall can also perform advanced services such as NATing and packet payload inspection. Therefore it is easy to see that a DMZ offers a higher level of protection to the computers that are part of the perimeter and internal networks.

Two-Router Configuration

Another interconnection of subnetworks is the two-router configuration.[9] This system consists of an external router, a bastion host, an internal router, and an internal network. The *bastion host* is a computer that serves as a filter and/or proxy for computers located in the internal network.

Before describing the specifics of the two-router configuration, let's define the duties of a bastion host. A bastion host is the first device any external computer will contact before accessing a computer in the internal network. Therefore the bastion host is fully exposed to the Internet and should be made as secure as possible. There are several types of bastion hosts, including victim machines that provide insecure but necessary services. For our discussion the bastion host will provide proxy services, shielding (to a limited degree) internal computers from external threats.

For the two-router configuration, the external network connects to the external router, which connects to the bastion host. The bastion host then connects to the internal router, which also connects to the internal network. The routers can provide limited filtering, whereas the bastion

8. J.R. Vacca and S. R. Ellis, *Firewalls Jumpstart for Network and Systems Administrators*, Elsevier, 2005.

9. J.R. Vacca and S. R. Ellis, *Firewalls Jumpstart for Network and Systems Administrators*, Elsevier, 2005.

host provides a variety of proxy services—for example, HTTP, SSH, IRC, and FTP. This provides some level of security, since attackers are unaware of some internal network details. The bastion host can be viewed as a part of a very small perimeter network.

Compared to the DMZ, a two-router system provides less security. If the bastion host is compromised, the computers in the internal network are not immediately vulnerable, but it would only be a matter of time before they were. Therefore the two-router design should be limited to separating internal subnetworks. If the internal router is a firewall, the design is considerably more secure.

Dual-Homed Host

A *dual-homed host* system consists of a single computer separating the external network from internal computers.[10] Therefore the dual-homed computer needs at least two network interface cards (NICs). One NIC connects to the external network; the other connects to the internal network—hence the term *dual-homed*. The internal connection is generally a switch that connects the other internal computers.

The dual-homed computer is the location where all traffic arriving and departing the internal network can be processed. The dual-homed computer can perform various tasks such as packet filtering, payload inspection, NAT, and proxy services. Given the simple design and low cost, this setup is popular for home networks. Unfortunately, the dual-homed approach introduces a single point of failure. If the computer fails, then the internal network is isolated from the external network. Therefore this approach is not appropriate for businesses that rely on the Internet.

Network Configuration Summary

This section described various network configurations that can be used to provide varying levels of security. There are certainly variations, but this part of the chapter attempted to describe the most prevalent:

- *Demilitarized zones (DMZs)*. When correctly configured, DMZs provide a reasonable level of security. Servers that need to be available to the external network are placed outside the internal network but have a firewall between them and the external network.
- *Perimeter networks*. A perimeter network consists of a subnetwork of systems (again, those that need to be available to the external network) located outside the internal network. The perimeter subnetwork is separated from the external network by a router that can provide some basic packet filtering.
- *Two-router configuration*. The two-router configuration places a bastion host between the internal and external networks. One router is placed between the internal network and bastion host, and the other router is placed between the bastion host and the external network. The bastion host provides proxy services, which affords some security (but not much).
- *Dual-homed configuration*. A dual-homed configuration has one computer that has at least two network connections—one connected to the external network and another to the internal network. All traffic must transmit through the dual-homed system; thus is can act as a firewall, NAT, and/or IDS. Unfortunately, this system has a single point of failure.

12. FIREWALL INSTALLATION AND CONFIGURATION

Before a firewall is actually deployed, it is important to determine the required services and realize the vulnerabilities that may exist in the computer system that is to be secured. Determining the services requires a detailed understanding of how the computers in the network are interconnected, both physically and from a service-oriented perspective. This is commonly referred to as *object discovery*.

For example, given a database server, which services should the server provide? Which computers should be allowed to connect? Restated, which ports should be open and to whom? Often object discovery is difficult since it is common that a server will be asked to do various tasks over time. Generally a multiservice server is cheaper (one server providing Web, email, and database), but it is rarely more secure. For example, if a multiservice server is compromised via one service, the other services are vulnerable to attack. In other words, the rules in the firewall policy are usually established by the list of available services and secure computers.

Scanning for vulnerabilities is also helpful when you're installing a firewall. Several open-source tools are available to detect system vulnerabilities, including netstat, which shows open services. Why not simply patch the vulnerability? Perhaps the patch is not available yet, or perhaps the application is deemed necessary but it is simply insecure (FTP is an example). Network mappers such as Nessus are also valuable in showing what information about the internal network is available from the outside. Knowing the internal network layout is invaluable in attacking a system, since must modern attacks are multistaged. This means that one type of system vulnerability is typically leveraged to gain access elsewhere within the network.

10. J.R. Vacca and S. R. Ellis, *Firewalls Jumpstart for Network and Systems Administrators*, Elsevier, 2005.

A simple and unfortunately common security risk is a Web server that is connected to another internal server for data. Assume that Network File System (NFS) is used to gain access to remote data. If the Web server is compromised, which will probably occur at some time, then all the data inside the data server may be at risk (depending on how permissions have been set) and access to the data could be the true objective of the attacker. Therefore, understanding the interconnection of internal machines can help identify possible multistage attacks.

Of course the process of determining services, access rights, and vulnerabilities is not a one-time occurrence. This process should repeat over time as new computers, operating systems, users, and so on are introduced. Furthermore, firewall changes can cause disruption to legitimate users; these cases require tracing routes, defining objects, and reading policies. Managing a firewall and its policy requires constant vigilance.

13. SUPPORTING OUTGOING SERVICES THROUGH FIREWALL CONFIGURATION

As described in the first section, a firewall and the policy govern access to and from an internal network (the network being administered). A firewall applies a policy to arriving packets, then determines the type of access. The policy can be represented as an ordered set of rules; again, assume that the first-match criterion is used. When a packet arrives, it is compared to the first rule to determine whether it is a match. If it is, then the associated action is performed; otherwise the next rule is tested. Actions include accepting, denying, and logging the packet.

For a simple packet filter, each rule in the policy will describe a certain range of packet headers that it will match. This range of packets is then defined by describing certain parts of the packet header in the rule. For the Internet (TCP/IP networks) there are five such parts that can be described: source IP, source port, destination IP, destination port, and protocol.

Recall that the source IP is the address of the computer that originated the packet. The source port is the number associated with the application that originated the packet. Given the IP address and port number, it is possible to determine the machine and application, within reason. The destination IP and port number describe the computer and the program that will receive the packet. Therefore, given these four pieces of information, it is possible to control the access to and from a certain computer and program. The fifth piece of information is the communication protocol, UDP or TCP.

At this point it is important to also consider the direction of traffic. When referring to a packet, did it come from the external network and is it destined for an internal computer, or vice versa? If the packet is considered inbound, the source and destination addresses are in one order; outbound would reverse the order. Unfortunately, many firewalls will consider any arriving packet as inbound, regardless of where it originated (external or internal network), so the administrator must consider the direction when designing the policy. For example, iptables considers packets as locally or nonlocally generated. Locally generated packets are created at the computer running the firewall; all others are nonlocal, regardless of the source network.

Many firewalls can go beyond the five tuples (TCP/IP packet header parts) described. It is not uncommon to have a rule check the Medium Access Control (MAC) address or hardware address. This can be applied to filter-spoofed addresses. Filtering on the Type of Service (ToS) field is also possible to treat packets differently—for better service, for example.

As previously described, maintaining the state of a connection is important for filtering traffic. For example, maintaining state allows the returning traffic to be accepted if the request was initiated from the internal network. Note that in these simple cases we are only considering two computers communicating—for example, an internal workstation connecting to an external Web server.

Forms of State

The state of a connection can be divided into three main categories: new, established, and related. The new state indicates that this is the first packet in a connection. The established state has observed traffic from both directions, so the minimum requirement is that the source computer sends a packet and receives a packet in reply. The new state will change to *established* once the reply packet is processed by the firewall.

The third type of state is *related*, which is somewhat complicated. A connection is considered related if it is associated with an established connection. Therefore an established connection may create a new connection, separate from the original, which is considered related. The common example of this process is the File Transfer Protocol (FTP), which is used to transmit data from a source computer to a destination computer. The process begins with one connection from source to destination on port 21, the command connection. If there is data to be transferred, a second connection is created on port 20 for the data. Hence the data connection is related to the initial control connection. To simplify the firewall policy, it is possible to add a single rule to permit related connections.

In the previous example, the two computers communicating remained the same, but new connections were created, which can be managed in a table. However,

understanding related connections is problematic for many new services. One example is the Common Object Resource Broker Architecture (CORBA), which allows software components to be executed on different computers. This communication model may initiate new connections from different computers, similar to peer-to-peer networking. Therefore it is difficult to associate related connections.

Payload Inspection

Although firewalls originally only inspected the packet header, content filtering is increasingly commonplace. In this case the packet payload (also called *contents* or *data)* is examined for certain patterns (analogous to searching for certain words on a page). These patterns, or signatures, could be for inappropriate or illegal content, spam email messages, or intrusion attempts. For example, it is possible to search for certain URLs in the packet payload.

The patterned searched for is often called a *signature*. If the pattern is found, the packet can be simply dropped, or the administrator may want to log the connection. In terms of intrusion signatures, this includes known patterns that may cause a buffer overflow in a network service.

Content filtering can be used to provide differentiated services as well. For example if the firewall can detect that a connection is used for multimedia, it may be possible to provide more bandwidth or disconnect it, depending on the policy. Of course, content filtering assumes that the content is available (readable), which is not the case when encryption is used. For example, many worms encrypt their communications to prevent content filtering at the firewall.

Examining the packet payload normally requires significantly more processing time than normal header inspection. A signature may actually contain several patterns to match, specifying where they should occur relative to the packet beginning and the distance between patterns in the signature. This is only a short list of potential signature characteristics.

A signature can also span multiple packets—for example, a 20-byte signature could occur over two 10-byte IP fragments. Recall that IP may fragment packets based on the maximum transfer unit (MTU) of a link. Therefore the system may have to reassemble fragments before the scanning can begin. This necessary reassembly will further delay the transmission of data, which is problematic for certain types of applications (for example, multimedia). However, at this point, the discussion is more about intrusion detection systems (IDSs) than firewalls.

Over the years several techniques have been developed to decrease the amount of time required for payload inspection. Faster searching algorithms, dedicated hardware, and parallel searching techniques have all shown promise in this regard. However, payload inspection at high bandwidths with low latency often requires expensive equipment.

14. SECURE EXTERNAL SERVICES PROVISIONING

Often we need a server that will provide services that are widely available to the external network. A Web server is a simple example of providing a service (Web pages) to a potentially large set of users (both honest and dishonest). As a result the server will be subjected to malicious intrusion attempts during its deployment.

Therefore systems that provide external services are often deployed on the edge or perimeter of the internal network. Given the location, it is it important to maintain secure communications between it and other servers. For example, assume that the Web server needs to access a database server for content (PHP and MySQL); the connection between these machines must be secure to ensure proper operation.

A common solution to secure communications is the use of a virtual private network (VPN), which uses encryption to tunnel through an insecure network and provide secrecy. Advanced firewalls can create VPNs to different destinations, including mobile users. The first and most popular protocol for VPN is Internet Security Protocol (IPsec), which consists of standards from IPv6 ported to IPv4.

15. NETWORK FIREWALLS FOR VOICE AND VIDEO APPLICATIONS

The next generation of network applications is expected to better leverage different forms of media. This is evident with the increased use of Voice over IP (VoIP) instead of traditional line-line telephones. Teleconferencing is another application that is seeing a steady increase in use because it provides an easy method for collaborating with others.

Teleoperations is another example that is seeing recent growth. These applications allow operators to control equipment that is at another location over the network (for example, telemedicine). Of course these examples assume that the network can provide QoS guarantees, but that is a separate discussion.

Generally speaking, these applications require special handling by network firewalls. In addition, they normally use more than one connection. For example, the audio, video, and control information of a multimedia application often uses multiple network connections.

Multimedia applications also use multiple transport protocols. Control messages can be sent using TCP, which provides a reliable service between the sender and receiver. The media (voice and/or video) is typically sent using UDP. Often Realtime Transport Protocol (RTP) is used, but this protocol is built on UDP. UDP is unreliable but faster than TCP, which is more important for multimedia applications.

As a result, these connections must be carefully managed by the firewall to ensure the proper operation of the application. This includes maintaining state across multiple connections and ensuring that packets are filtered with minimal delay.

Packet Filtering H.323

There are a few multimedia standards for transmitting voice and video over the Internet. Session Initiation Protocol (SIP) and H.323 are two examples commonly found in the Internet. The section briefly describes H.323 to illustrate the support required by network firewalls.

H.323 is the International Telecommunications Union (ITU) standard for videoconferencing. It is a high-level standard that uses other lower-level standards for the actual setup, transmission, control, and tear-down of a videoconference. For example, G.711 is used for encoding and decoding speech, and H.245 is used to negotiate the connections.

During H.323's operation, one port will be used for call setup using the static port 1720 (easy for firewalls). Each datastream will require one dynamically allocated TCP port for control and one dynamically allocated UDP port for data. As previously described, audio and video are transmitted separately.

Therefore an H.323 session will generate at least eight dynamic connections, which makes packet processing at the firewall very difficult. How does a firewall know which ports to open for an H.323 session? This is referred as a *lack of symmetry* between the computer located in the internal network and the computer located in the external network.

A stateful firewall can inspect the packet payloads and determine the dynamic connection port numbers. This information (negotiated port numbers) is placed in higher-level protocols, which are difficult to quickly parse and can be vendor specific.

In 2005 the ITU ratified the H.460.17/.18/.19 standards, which describe how to allow H.323 to traverse a firewall (or a NAT router/firewall, which essentially has the same problem). H.460.17 and H.460.18 deal with signaling, whereas H.460.19 concerns media. The H.460 standards require the deployment of stateful firewalls and updated H.323 equipment. This is a solution, but it remains a complex problem.

16. FIREWALLS AND IMPORTANT ADMINISTRATIVE SERVICE PROTOCOLS

There are a large number of administrative network protocols that are used to manage computer systems. These protocols are typically not complex to control at the firewall since dynamic connections are not used and little state information is necessary. The administrator should be aware of these services when designing the security policy, since many can be leveraged for attacks. This section reviews some of these important protocols.

Routing Protocols

Routing protocols are used to distribute routing information between routing devices. This information will change over time based on network conditions; therefore this information is critical to ensure that packets will get to their destinations. Of course, attackers can also use routing protocols for attacks. For example, maliciously setting routes such that a certain network is not reachable can be considered a denial-of-service (DoS) attack. Securing routers and routing protocols is a continuing area of research. The firewall can help prevent these attacks (typically by not forwarding such information).

In considering routing protocols, it is important to first determine which devices in the internal network will need to receive and submit routing information. More than likely only devices that are directly connected to the external network will need to receive and respond to external routing changes—for example, the gateway router(s) for the internal network. This is primarily due to the hierarchical nature of routing tables, which does not require an external host to know the routing specifics of a distant subnetwork. As a result, there is typically no need to forward routing information from the external network into the internal network, and vice versa.

Routing Information Protocol (RIP) is the oldest routing protocol for the Internet. The two versions of RIP differ primarily by the inclusion of security measures. RIPv1 is the original protocol, and RIPv2 is the same but supports classless addresses and includes some security. Devices that use RIP will periodically (approximately every 30 seconds) broadcast routing information to neighboring hosts. The information sent by a host describes the devices they are directly connected to and the cost. RIP is not very scalable so is primarily used for small networks. RIP uses UDP to broadcast messages; port 520 is used by servers, whereas clients use a port above 1023.

Another routing protocol is Open Short Path First (OSPF), which was developed after RIP. As such OSPF is considered an improvement because it converges faster and it incorporates authentication. Interestingly, OSPF is not built on the transport layer but instead talks directly

to IP. It is considered protocol 89 by the IP layer. OSPF messages are broadcast using two special multicast IP addresses: 224.0.0.5 (all SPF/link state routers) and 224.0.0.6 (all designated routers). The use of multicast addresses and setting the packet Time to Live (TTL) to one (which is done by OSPF) typically means a firewall will not pass this routing information.

Internet Control Message Protocol

Internet Control Message Protocol (ICMP) is used to send control messages to network devices and hosts. Routers and other network devices monitor the operation of the network. When an error occurs, these devices can send a message using ICMP. Messages that can be sent include destination unreachable, time exceeded, and echo request.

Although ICMP was intended to help manage the network, unfortunately attackers can use it as well. Several attacks are based on ICMP messages since they were originally allowed through the firewall. For example, simply forging a "destination unreachable" ICMP message can cause problems.

The program ping is one program that uses ICMP to determine whether a system is connected to the Internet (it uses the ICMP messages Echo Request and Echo Reply). However, this program can also be used for a smurf attack, which causes a large number of unsolicited ping replies to be sent toward one computer. As a result most firewall administrators do not allow ping requests or replies across the firewall.

Another program that uses ICMP is traceroute, which determines the path (list of routers) between a source and destination. Finding the path is done by sending multiple packets, each with an increasing TTL number (starting at one). When a router encounters a packet that it cannot forward due to the TTL, an ICMP message is sent back to the source. This reveals the router on the path (assuming that the path remains the same during the process). Most administrators do not want to provide this information, since it can show addresses assigned to hosts, which is useful to attackers. As a result firewalls are often configured to only allow traceroute requests originating from the internal network or limiting replies to traceroute originating from known external computers.

ICMP is built on the IP layer, like TCP and UDP. A firewall can filter these messages based on the message code field, which is a number that corresponds to each type of error message. Although this section described the problems with allowing ICMP messages through the firewall, an administrator may not want to block all ICMP packets. For example, Maximum Transfer Unit (MTU) messages are important for the transmission of packets and probably should be allowed.

Network Time Protocol

Network Time Protocol (NTP) is a protocol that allows the synchronization of system clocks (from desktops to servers). Having synchronized clocks is not only convenient but required for many distributed applications. Therefore the firewall policy must allow the NTP service if the time comes from an external server.

NTP is a built-on UDP, where port 123 is used for NTP server communication and NTP clients use port 1023 (for example, a desktop). Unfortunately, like many legacy protocols, NTP suffers from security issues. It is possible to spoof NTP packets, causing clocks to set to various times (an issue for certain services that run periodically). There are several cases of NTP misuse and abuse where servers are the victim of DoS attacks.

As a result, if clock synchronization is needed, it may be better to provide an internal NTP server (master clock) that synchronizes the remaining clocks in the internal network. If synchronization is needed by an NTP server in the Internet, consider using a bastion host.

Central Log File Management

Almost every operating system maintains a system log where important information about a system's state is reported. This log is a valuable resource for managing system resources and investigating security issues.

Given that almost every system (especially a server) generates log messages, having this information at a central location is beneficial. The protocol syslog provides this functionality, whereby messages can be forwarded to a syslog server, where they are stored. An attacker will commonly attempt to flood the syslog server with fake messages in an effort to cover their steps or to cause the server disk to fill, causing syslog to stop.

Syslog runs on UDP, where syslog servers listen to UDP port 514 and clients (sending log messages) use a port above 1023. Note that a syslog server will not send a message back to the client, but the syslog log server can communicate, normally using port 514.

Generally allowing syslog communication between the external and internal network is not needed or advised. Syslog communications should be limited to internal computers and servers; otherwise a VPN should be used to prevent abuse from others and to keep the information in the messages private.

Dynamic Host Configuration Protocol

The Dynamic Host Configuration Protocol (DHCP) provides computers essential information when connecting to an IP network. This is necessary because a computer (for example, a mobile laptop) does not have an IP address to use.

The computer needing an IP address will first send a broadcast request for an IP address. A DHCP server will reply with the IP address, netmask, and gateway router information the computer should use. The address provided comes from a pool of available IP addresses, which is managed by the DHCP server. Therefore the DHCP provides a method of sharing IP addresses among a group of hosts that will change over time.

The actual exchange of information is more elaborate than described here, but this is enough information for our discussion. In general the DHCP server providing addresses will be located in the internal network. As a result, this information should not be transmitted across the firewall that separates the internal and external networks. Why would you want to provide IP addresses to computers in the external network?

17. INTERNAL IP SERVICES PROTECTION

Domain Name Server (DNS) provides the translation between the hostname and the IP address, which is necessary to send packets in the Internet. Given the number of hostnames in the Internet, DNS is built on a hierarchical structure. The local DNS server cannot store all the possible hostnames and IP addresses, so this server will need to occasionally request a translation from another DNS server located in the external network. As a result it is important to configure the firewall to permit this type of lookup.

In many cases the service provider provides the address of a DNS server that can be used to translate external hostnames. There is no need to manage a local DNS server in this case. However, it is possible to manage a local DNS, which allows the internal network to use local hostnames (these can be published to the external network). Some advanced firewalls can provide DNS, which can help hide internal computer hostnames and IP addresses. As a result, external computers have a limited view of the internal network.

Another important service that can be provided by the firewall is Network Address Translation (NAT). NAT is a popular method for sharing a smaller set of IP addresses across a larger number of computers. Recall that every packet has a source IP, source port, destination IP, and destination port. Assume that a small network only has one external IP address but has multiple computers that need to access the Internet. Note the external address is a routable address, whereas the internal computers would use a private address (addresses have no meaning outside the internal network). NAT will allow the internal machines to share the single external IP address.[11]

When a packet arrives from a computer in the internal network, its source address is replaced with the external address, as shown in Figure e29.4. The packet is sent to the destination computer, which returns a packet. The return packet has the external address (which is routable), so it is forwarded to the firewall. The firewall can then replace the external destination address with the correct

11. B. Hickman, D. Newman, S. Tadjudin, and T. Martin, *Benchmarking Methodology for Firewall Performance*, IETF RFC 3511, 2003.

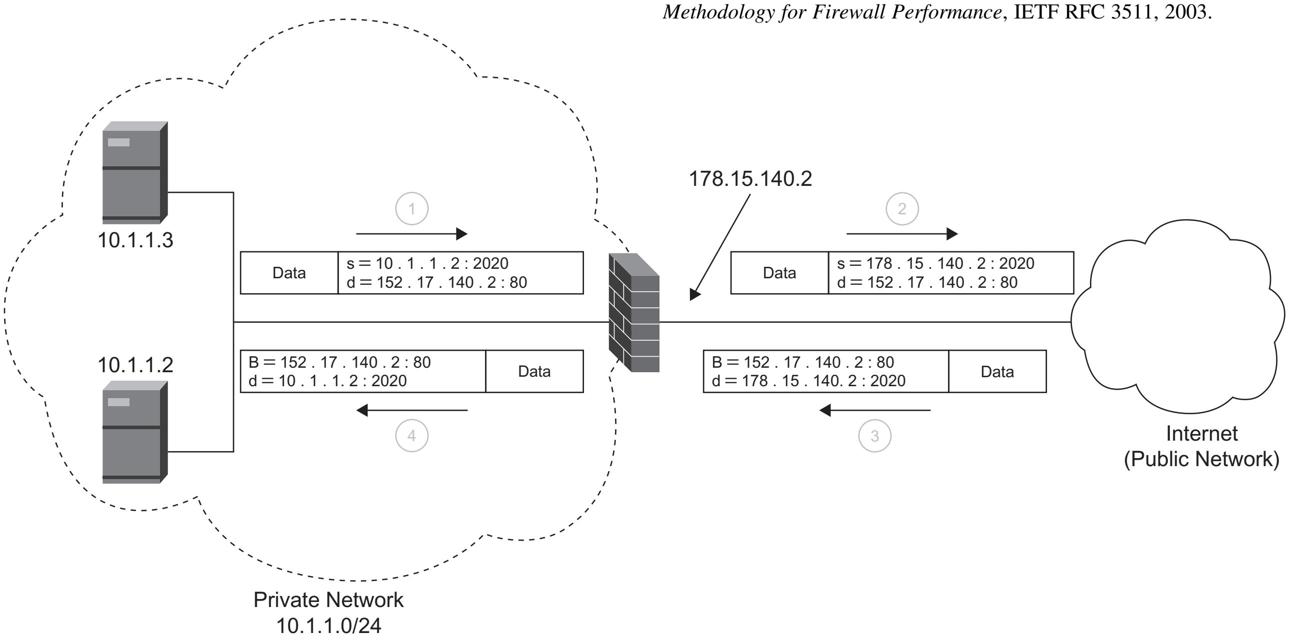

FIGURE e29.4 Example source Network Address Translation (NAT). The connection originates from a computer in the internal network and is sent to a computer in the external network. Note the address and port number exchange performed at the firewall.

internal destination address. What if multiple internal machines send a packet to a server in the external network? The firewall will replace the source address with the external address, but how will the firewall differentiate the return packets? NAT will also change the source port number, so each connection can be separated.

The NAT process described in the preceding paragraph is *source NAT*,[12] which works for packets initiated in the internal network. There is also *destination NAT*, which works in a similar fashion for packets initiated in the external network. In this case the firewall needs to know which machine to forward packets to in the internal network.

18. FIREWALL REMOTE ACCESS CONFIGURATION

As described in the first section, firewalls are deployed to help maintain the privacy of data and authenticate the source. Privacy can be provided using encryption, for which there are several possible algorithms to use. These algorithms can be categorized as either secret key or public key. Secret key techniques use the same key to encrypt and decrypt information. Examples include IDEA, RC4, Twofish, and AES. Though secret key algorithms are fast, they require the key to be distributed between the two parties in advance, which is not trivial.

Public key encryption uses two keys—one to encrypt (the public key) and another to decrypt (the private key). The public key can be freely available for others to use to encrypt messages for the owner of the private key, since only the private key can decrypt a message. Key management sounds easy, but secure key distribution is difficult. How do you know the public key obtained is the correct one? Perhaps it is a man-in-middle attack. The Public Key Infrastructure (PKI), one method of distributing public keys, depends on a system of trusted key servers.

Authentication is another important component of security; it attempts to confirm a person is who he or she claims to be. This can be done based on what the user has (ID card or security token) or by something a person knows (for example, a password). A very familiar method of authentication is requesting a username and password, which is common for VPNs.

Secrecy and authentication are also important when an entity manages multiple separate networks. In this case the administrator would like to interconnect the networks but must do so using an insecure network (for example, the Internet).

Tunneling from one firewall to another firewall can create a secure interconnection. This can be done using application proxies or VPN. Application firewalls implement a proxy for each application supported. A user first contacts the firewall and authenticates before connecting to the server. The firewall then connects to the destination firewall, which then connects to the destination server. Three connections are thus involved.

An alternative is to construct a VPN from one firewall to another. Now a secure connection exists between the two networks. However, note that the VPN could also be used as an easy connection for an attacker who has successfully broken into one of the networks.

It is also important to note that tunneling can be used to transport packets over a network with a different transport protocol—for example, carrying TCP/IP traffic over Frame Relay.

19. LOAD BALANCING AND FIREWALL ARRAYS

As network speeds continue to increase, firewalls must continue to process packets with minimal delay (latency). Unfortunately, firewalls that can operate at these extreme data rates are also typically very expensive and cannot easily be upgraded to meet future demands. Load-balancing firewalls can provide an answer to this important problem.[13]

Load balancing (or *parallelization)* provides a scalable firewall solution for high-bandwidth networks and/or low-latency applications. This approach consists of an array of firewalls that process arriving packets in parallel. A simple system would consist of two load balancers connected to an array of firewalls, where each firewall is identically configured (same firewall policy), as depicted in Figure e29.5. One balancer connects to the Internet, then to the array (arriving traffic); the other balancer connects to the internal network, then to the array (departing traffic). Of course, one load balancer can be used instead of two separate load balancers.

When a packet arrives, it is sent to a firewall that currently has the lightest load (fewest number of packets awaiting processing), hence the term *load balancing*. As a result, the amount of traffic each firewall must process is roughly $1/n$ of the total traffic, where n is the number of firewalls in the array.

As with any new firewall implementation, the integrity of the policy must be maintained. This means that given a policy, a traditional single firewall and a load-balancing firewall will accept the same packets and deny the same packets. For static rules, integrity is provided, since the policy is duplicated at every firewall; therefore the set of accepted and denied packets at each firewall is

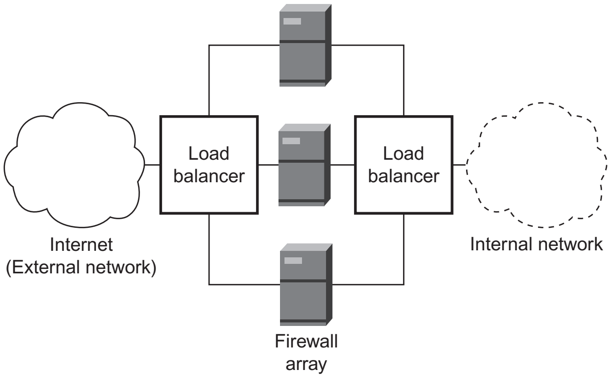

FIGURE e29.5 Load-balancing firewall array consisting of a three-firewall array and a load balancer.

also the same. As will be discussed in the next sections, maintaining integrity for stateful rules is not easy.

Load Balancing in Real Life

A simple supermarket analogy can help describe the system and the potential performance increase. Consider a market consisting of an array of *n* cashiers. As with the firewall system, each cashier in the market is identical and performs the same duties. When a customer wants to pay for her items, she is directed to the cashier with the shortest line. The load balancer is the entity that would direct the customer, but in reality such a person rarely exists. A customer must guess which line is actually the best to join, which as we all know is not simple to determine.

Obviously, as more cashiers are added, the market can check out more customers. This is akin to increasing the bandwidth of the firewall system. Another important advantage of a load-balancing system is robustness. Even if a cashier takes a break (or a firewall in the array fails), the system will still function properly, albeit more slowly.

How to Balance the Load

An important problem with load-balancing firewalls is how to quickly balance the lines (queues) of packets. We are all aware that customers require different amounts of time to check out of a market. This is dependent on the number of items (which is observable) and their ability to pay (not easily observable). Similarly, it is difficult to determine how much time a packet will require at a firewall (for software-based systems). It will depend on the number of rules, organization of the rules, and which rule the packet will match.

A more important problem with load balancing is how to maintain state. As described in the preceding sections, some firewall rules will maintain the state of a connection. For example, a firewall rule may allow traffic arriving from the Internet only if an internal computer requested it. If this is the case, a new temporary rule will be generated to handle traffic arriving from the Internet. In a parallel system, where should this rule reside? Which firewall? The objective is to ensure that the integrity of the policy is maintained in the load-balancing system.

To use the market analogy again (and this will be a stretch), assume that a mother leaves her credit card with one cashier, then sends her children into the market to buy certain items. When the children are ready to pay for their items they must go to the cashier that has the credit card. If the children don't know which cashier has the credit card the load balancer must not only balance lines but also check a list to make certain the children join the correct line.

Maintaining state increases the amount of time the load balancer will spend per packet, which increases the latency of the system. An alternative solution is it to replicate the stateful rules across every firewall (or the credit card across every cashier). This requires an interconnection and state-aware program per firewall. Maintaining network connections is also difficult for applications that dynamically create new connections. Examples include FTP (one connection for control, the other for data), multimedia, and CORBA. Again, a new rule must be added to handle the new traffic.

Advantages and Disadvantages of Load Balancing

Given these issues, firewall load balancing is still done. There are several advantages and disadvantages to this approach. Disadvantages of load balancing include:

- *Load balancing is not trivial*. The load balancer seeks to ensure that the lines of packets across the array of firewalls remains equal. However, this assumes that the balancer can predict how much time a packet will require.
- *Maintaining state is difficult*. All packets that belong to a session will need to traverse the same firewall, or state information must be shared across the firewalls. Either solution is difficult to manage.

There are several advantages to load balancing:

- *Scalable solution for higher throughput*. If higher throughput is needed, adding more firewalls is simple and cost effective.
- *Robustness*. If a firewall fails in the array, the integrity of the system remains. The only loss is throughput.
- *Easy policy management*. If the rules change, simply update the policy at each firewall.

The load balancer can be implemented in software or hardware. Hardware load balancers provide better performance, but they will also have a much higher price.

20. HIGHLY AVAILABLE FIREWALLS

As previously discussed, a network firewall is generally considered easier to manage than multiple host-based firewalls. The administrator only manages one firewall and one policy, but this design also introduces a single point of failure. If the network firewall fails in the system, the entire internal network is isolated from the Internet. As a result, there is a real need to provide a highly available, or robust, firewall system.

The load-balancing system described in the previous section provides a greater degree of robustness. If a firewall in the array fails, the system is still functional; however, the capacity of the system is reduced, which is considered acceptable under the circumstances. Unfortunately, the design still has a single point of failure—the load distributor. If the load distributor fails, the entire system fails.

A simple solution to this problem simply replicates the load distributor. The incoming connection is duplicated to both load distributors, and the distributors are then connected to the firewalls in the array. The distributors are interconnected via a lifeline to detect failure and possibly share information.

Load Balancer Operation

The two load balancers described in the previous section can operate in one of two modes: active-backup or active-active. In active-backup mode, one balancer operates as normal distributing packets to minimize delays and maintain state information. The second distributor is in backup mode and monitors the status of the active load balancer and duplicates any necessary state information. Upon load-balance failure, the backup device can quickly take over operation.

In contrast, active-active operation operates both load balancers in parallel. When a packet arrives at the system, it is processed by one of the load balancers, which forwards the packet to a firewall in the array. Of course, this seems as though there will be a load balancer for the load balancers, but this is not necessary. Under active-active mode, the load balancers use the lifeline to synchronize and determine which packets to process. Although the active-active mode can increase performance by using both load balancers simultaneously, it is more difficult to implement and complex to manage.

Interconnection of Load Balancers and Firewalls

In our simple example, the additional load balancer requires double the number of ports per firewall (one per load balancer). This design provides greater robustness but may also be cost prohibitive.

An alternative solution uses active-active mode and divides the array into two equal groups. One group is then connected to one load-balancer and the other group is connected to the other. For example, consider an array of six firewalls. Three firewalls would be connected to one load balancer and the other six firewalls connected to the second load balancer. Although this design only requires one port per firewall (on one side), if a load balancer fails, half the firewalls are nonoperational.

21. FIREWALL MANAGEMENT

Once a firewall has been deployed and policy created, it is important to determine whether it is providing the desired security. Auditing is the process of verifying the firewall and policy and consists of two steps. First, the administrator should determine whether the firewall is secure. If an attacker can exploit the firewall, the attacker has a significant advantage. Consider the information that can be gained just from knowing the firewall policy.

The firewall should be in a secure location and have the latest security patches (recall that many firewalls are implemented in software). Also ensure that the firewall only provides the necessary services, such as SSH, if remote access to the firewall is needed. Exploiting a firewall operating system or provided services is the most common method for breaking into a firewall. Therefore the services and access should be tightly controlled. User authentication with good passwords and secure connections should always be used.

Once the firewall has been secured, the administrator should review the policy and verify that it provides the security desired. Does it block the illegitimate traffic and permit legitimate traffic? This is not a trivial task, given the first-match criterion and the number of rules in the policy. It is easy to create firewall policies with anomalies, such as shadowing (a subsequent rule that is never matched because of an earlier rule). Some software packages are available to assist this process, but in general it is a difficult problem.

An administrator should periodically audit the firewall rules and test the policy to verify that the system performs as expected. In addition, the system should undergo penetration testing to verify correct implementation. This includes seeded and blind penetration testing. *Seeded testing* includes detailed information about the network and configuration, so target systems and services can be

tested. *Blind testing* is done without any knowledge of the system, so it is more complete but also more time consuming.

Keeping backups of configurations and policies should be done in case of hardware failure or an intrusion. Logging at the firewall should also be performed, which can help measure performance. In addition, logs can show connections over time, which is useful for forensics and verifying whether the security policy is sufficient.

22. SUMMARY

Network firewalls are a key component of providing a secure environment. These systems are responsible for controlling access between two networks, which is done by applying a security policy to arriving packets. The policy describes which packets should be accepted and which should be dropped. The firewall inspects the packet header and/or the payload (data portion).

There are several different types of firewalls, each briefly described in this chapter. Firewalls can be categorized based on what they inspect (packet filter, stateful, or application), their implementation (hardware or software), or their location (host or network). Combinations of the categories are possible, and each type has specific advantages and disadvantages.

Placement of the firewall with respect to servers and internal computers is key to the way these systems will be protected. Often servers that are externally available, such as Web servers, will be located away from other internal computers. This is often accomplished by placing these servers in a demilitarized zone (DMZ). A different security policy is applied to these computers so the access between computers in the DMZ and the internal network is limited.

Improving the performance of the firewall can be achieved by minimizing the rules in the policy (primarily for software firewalls). Moving more popular rules near the beginning of the policy can also reduce the number of rules comparisons that are required. However, the order of certain rules must be maintained (any rules that can match the same packet).

Parallel firewalls can provide greater performance improvements. These systems consist of a load balancer and an array of firewalls, where all the firewalls in the array are identical. When a packet arrives at the system, it is sent to one of the firewalls in the array. The load balancer maintains short packet queues, which can provide greater system bandwidth and possibly a lower latency.

Regardless of the firewall implementation, placement, or design, deployment requires constant vigilance. Developing the appropriate policy (set of rules) requires a detailed understanding of the network topology and the necessary services. If either of these items change (and they certainly will), that will require updating the policy. Finally, it is important to remember that a firewall is not a complete security solution but is a key part of a security solution.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Network firewalls are a vital component for maintaining a secure environment and are often the first line of defense against attack.
2. True or False? When a packet arrives at a firewall, a hacker policy is applied to determine the appropriate action.
3. True or False? Multiple rules of a single firewall policy may match a packet—for example, a packet could match rules 2, 6, and 7 of the policy.
4. True or False? For most firewalls, the first rule that matches a packet is not typically applied.
5. True or False? Given that a network firewall will not inspect all packets transmitted between multiple networks, these devices need to determine the appropriate match with minimal delay.

Multiple Choice

1. What refers to how often the rule is a match?
   A. Worm
   B. Virus
   C. Backdoor
   D. More popular
   E. User-level Rootkit
2. What is the most basic type of a firewall since it only filters at the network and transport layers (layers two and three)?
   A. Backdoor
   B. Virus
   C. Worm
   D. Packet filter
   E. User-level Rootkit
3. What perform the same operations as packet filters, but also maintain state about the packets that have arrived?
   A. Stateful firewalls
   B. Virus
   C. Worm
   D. Backdoor

   E. User-level Rootkit
4. What can filter traffic at the network, transport, and application layer?
   A. Application layer firewalls
   B. Virus
   C. Worm
   D. Backdoor
   E. User-level Rootkit
5. What can also be categorized based on where they are implemented or what they are intended to protect—host or network?
   A. Trojan Horse
   B. Firewalls
   C. Worm
   D. Backdoor
   E. User-level Rootkit

EXERCISE

Problem

Create a firewall policy that specifies how firewalls should handle inbound and outbound network traffic.

Hands-On Projects

Project

Identify all requirements that should be considered when determining which firewall to implement.

Case Projects

Problem

Create rulesets that implement the organization's firewall policy while supporting firewall performance.

Optional Team Case Project

Problem

Manage firewall architectures, policies, software, and other components throughout the life of the firewall solutions.

Chapter 30

Penetration Testing

Sanjay Bavisi
EC-Council

1. INTRODUCTION

Last year I walked into a restaurant in Rochester, New York, with a business partner; I was wearing an EC-Council official polo shirt. The back of the shirt was embroidered with the words "Licensed Penetration Tester." On reading those words on my shirt, a group of young executives seated behind me started an intense dialogue among themselves.

They were obviously not amused at my "behavior," since that was a restaurant for decent people! On my way out, I walked up to them and asked if they were amazed at what that statement meant. They replied "Absolutely!" When I explained to them the meaning of a Licensed Penetration Tester, they gave a loud laugh and apologized to me. They admitted that they had thought I was a pervert.

Each time I am at an airport, I get some stares when I put on that shirt. So the question is, what is penetration testing?

2. WHAT IS PENETRATION TESTING?

Penetration testing is the exploitation of vulnerabilities present in an organization's network. It helps determine which vulnerabilities are exploitable and the degree of information exposure or network control that the organization could expect an attacker to achieve after successfully exploiting a vulnerability. No penetration test is or ever can be "just like a hacker would do it," due to necessary limitations placed on penetration tests conducted by "white hats." Hackers don't have to follow the same rules as the "good guys" and they could care less whether your systems crash during one of their "tests." We'll talk more about this later. Right now, before we can talk any more about penetration testing, we need to talk about various types of vulnerabilities and how they might be discovered.

Before we can exploit a vulnerability in a penetration test, we have to discover what vulnerabilities exist within (and outside of) the organization. A vulnerability is a potential weakness in an organization's security. I use the term "potential" because not all vulnerabilities are exploitable or worth exploiting. A flaw may exist and may even be documented, but perhaps no one has figured out (yet) how to exploit it. Some vulnerabilities, although exploitable, might not yield enough information in return for the time or resources necessary to exploit them. Why break into a bank and steal only a dollar? That doesn't make much sense, does it?

Vulnerabilities can be thought of in two broad categories: logical and physical. We normally think of logical vulnerabilities as those associated with the organization's computers, infrastructure devices, software, or applications. Physical vulnerabilities, on the other hand, are normally thought of as those having to do with either the actual physical security of the organization (such as a door that doesn't always lock properly), the sensitive information that "accidentally" ends up in the dumpster, or the vulnerability of the organization's employees to social engineering (a vendor asking to use a computer to send a "quick email" to the boss).

Logical vulnerabilities can be discovered using any number of manual or automated tools and even by browsing the Internet. For those of you who are familiar with Johnny Long's *Google Hacking* books: *"Passwords*, for the *love of God!!!* Google found *passwords!"* The discovery of logical vulnerabilities is usually called *security scanning*, *vulnerability scanning*, or just *scanning.* Unfortunately, there are a number of "security consultants" who run a scan, put a fancy report cover on the output of the tool, and pass off these scans as a penetration test.

Physical vulnerabilities can be discovered as part of a physical security inspection, a "midnight raid" on the organization's dumpsters, getting information from employees, or via unaccompanied access to a usually nonpublic area (I really need to use the bathroom!).

Vulnerabilities might also exist due to a lack of company policies or procedures or an employee's failure to follow the policy or procedure. Regardless of the cause of the vulnerability, it might have the potential to compromise the organization's security. So, of all the vulnerabilities that have been discovered, how do we know which ones pose the greatest danger to the organization's

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00030-1

network? We test them! We test them to see which ones we can exploit and exactly what could happen if a "real" attacker exploited that vulnerability.

Because few organizations that I know of have enough money, time, or resources to eliminate every vulnerability discovered, they have to prioritize their efforts; this is one of the best reasons for an organization to conduct a penetration test. At the conclusion of the penetration test, they will know which vulnerabilities can be exploited and what can happen if they are exploited. They can then plan to correct the vulnerabilities based on the amount of critical information exposed or network control gained by exploiting the vulnerability. In other words, a penetration test helps organizations strike a balance between security and business functionality. Sounds like a perfect solution, right? If only it were so!

There are organizations that do not care about the "true risks" that their organizations face. Instead, they are more interested in being able to tell their shareholders or their regulating agencies that they've conducted a penetration test and "passed" it. If the penetration test is structured so that only certain systems are tested, or if the test is conducted during a known timeframe, the test results will be favorable to the organization, but the test isn't a true reflection of its network security posture. This kind of "boutique testing" can lead to a false sense of security for the organization, its employees, and its stakeholders.

3. HOW DOES PENETRATION TESTING DIFFER FROM AN ACTUAL "HACK?"

Earlier, I mentioned that penetration testing isn't and never can be "just like a hacker would do it." How come? Except in the case of "directed" sabotage or espionage, it's not personal between your organization and attackers. They don't care who you are, where you are, or what your organization does to earn its living. They just want to hack something. The easier it is to attack your network, the more likely it is that you'll be a target. Ask your network administrator to look at the network intrusion detection logs (or look at them yourself if you're a network admin). See how many times in a 24-hour period your organization's network gets scanned for potential vulnerabilities.

Once an attacker has decided that you're his or her (yes, there *are* female hackers—good ones, too!) next target, they may take weeks or months to perform the first step of an attack: reconnaissance. As a penetration tester or company providing penetration testing services, I doubt that you're going to get hired to spend six months doing reconnaissance and another couple of months conducting an attack. So, the first difference between a penetration test and a real attack is the length of time taken to conduct all the activities needed to produce a successful outcome. As "good guys," we don't have the luxury of time that the "bad guys" do. So we're handicapped to begin with. The two things I tell clients are:

1. I cannot spend the months planning to attack you like a real hacker can
2. I cannot break the law, I am limited by a code of ethics, and have to maintain "ethical" boundaries.

In some (not all) cases, once attackers find a suitable vulnerability to attack, they will. They don't care that the vulnerability resides on a mission-critical system, if the vulnerability will crash the system, or that the system might become unusable in the middle of the busiest time of day. If that vulnerability doesn't "pan out," they find another and try again. They keep it up until they run out of vulnerabilities that they can exploit, or they're discovered, or they manage to successfully breach the network or crash the system. Penetration test teams normally don't have this luxury, either. Usually the test team has *X* amount of time to find a vulnerability and get in or the test is over and the network is declared "safe and secure." If the test team didn't have enough time to test all the vulnerabilities—oh, well. The test is still over, they still didn't get in, and so our network *must* be safe! Few seem to think about the fact that a "real" attacker may, just by blind luck, choose one of the unable-to-be-tested-because-of-time-limitations vulnerabilities and be able to waltz right into the network without being detected. One of the most important things for a tester and/or clients to grasp is the fact that no test will find everything, there are always things that can be missed, be it due to time constraints, or the team did not have the right conditions to find the weakness. It is best to proceed with the understanding that there will always be things we might miss, our job as a tester is to find what we can within the scope of the assessment and time constraints. At the end of the day, the goal of the test is to provide the client a report that will assist them in improving their security posture, there is no such thing as perfect security and there will never be.

Some systems are declared "off limits" to testing because they're "too important to have crash" during a test. An organization may specify that testing can only occur during certain hours or on certain days because of a real or perceived impact on business operations. This is the second difference between a penetration test and a real attack: Hackers don't play by any rules. They attack what they want when they want and how they want. Just to be clear: I'm not advocating denial-of-service testing during the busiest time of an organization's day, or unrestricted testing at any time. I'm just trying to make a point that *no* system is too critical to test. From a hacker's perspective, there are no "off-limits" systems, just opportunities for attack. We'll talk more about differences between real attacks and penetration tests when we talk about the various types of testing in the next section. For example, in a bank or financial company you never get to

test their financial databases, there is just too much risk, and when that is the revenue that the company uses to survive they are not going to let you test it, and real hackers would not have this limitation.

4. TYPES OF PENETRATION TESTING

Some sources classify penetration testing into two types—internal and external—and then talk about the "variations" of these types of tests based on the amount of information the test team has been given about the organization prior to starting the test. Other sources use a reverse-classification system, typing the penetration test based on the amount of information available to the test team and then the location from which the test is conducted. I much prefer the latter method, since it removes any chance of misunderstanding about what testing is going to be conducted where. *Warning:* If you're planning to take the CISSP or some of the other network security certification examinations, stick with the "old skool" "classification by location, then type" definitions for penetration testing types and variations.

When a penetration test is conducted against Internet-facing hosts, it is known as *external testing*. When conducted against hosts inside the organization's internal network, it is known as *internal testing*. Obviously, a complete penetration test will encompass testing of both external and internal hosts. The "variations" of penetration tests are normally classified based on how much information the test team has been given about the organization. The three most commonly used terms for penetration types are *white-box*, *gray-box*, and *black-box testing*. Before we talk about these penetration testing variations, you need to understand that we can conduct any of them (white, gray, or black) either externally or internally. If we want a complete test, we need to test both externally *and* internally. Got it? Good! Now we can talk about what is involved with each type of testing.

We'll start with white-box testing. The "official" definition of white-box testing usually includes verbiage about providing information so as to be able to assess the security of a specific target or assess security against a specific attack. There are several problems with this definition in real life. The first is that it sounds as though you would only conduct a white-box test if you were looking to verify the security of one specific host or looking to verify the security of your network against one specific attack. But it would be foolhardy to test for only one vulnerability. Since the "variations" we're talking about are supposed to be centered on the amount of information available to the test team, let's look at a white-box test from an information availability perspective.

Who in your organization knows the most about your network? Probably the network administrator. Any organization that has recently terminated employment of a network administrator or member of the IT Department under less than favorable circumstances has a big problem. There is the potential that the organization's network could be attacked by this former employee who has extreme knowledge about the network. In a white-box test, therefore, the test team should be given about the same amount of information that a network administrator would have. Probably the team won't be given passwords, but they'll be given network ranges, topologies, and so on.

Gray-box testing, by "official" definition, provides "some" knowledge to the test team, about the sort of thing a normal, unprivileged user might have: hostnames, maybe a few IP addresses, the fact that the organization allows senior management to "remote" into the network, and so on. Common, though not necessarily public, knowledge about the "inner workings" of the organization's network is the level of information provided to the test team. Some sources claim that this testing type (as well as the information disclosed in a white-box test) "puts the tester at an advantage" over an attacker because the test team possesses information that an attacker wouldn't have. But that's not necessarily the case. Any organization that has terminated a "normal user" has the potential for an attack based on that user's inside knowledge of the network.

Now let's talk about everyone's favorite: black-box penetration testing. Again, we'll start with the common definition, which usually says something like "provides the test team with little or no information except for possibly the company name." The test team is required to obtain all their attack information from public sources such as the Internet. There's usually some sentence somewhere in the description that says how a black-box test is always much better than any other type of test because it most closely mimics the way an attacker would conduct an attack. The definition might be right (and I might even be inclined to agree with it) if the organization has never terminated a network admin or any other employee with network access. I might also be more in agreement with this train of thought if the majority of attacks were conducted by unknown persons from the far reaches of the globe instead of former employees or currently employed "insiders"!

Depending on what article or book you happen to be reading at the time, you might also see references to application penetration testing, Web penetration testing, shrink-wrap penetration testing, wireless penetration testing, telephony penetration testing, Bluetooth penetration testing ... and the list goes on. I've seen every possible device in a network listed as a separate penetration test. The bottom line is that if it's present in the network, an organization needs to discover what vulnerabilities exist on it and then test those vulnerabilities to discover what could happen if they're successfully exploited.

I guess since Morgan Kaufmann asked me to write this chapter, I can give you my opinion: I don't like black-box penetration testing. I don't want any network of mine tested "just like a hacker would do it." I want my network tested *better* than any hacker ever could, because I don't want to end up on the front page of *The New York Times* as the subject of a "latest breach" article. My client's data are much too important to take that chance.

The success of every penetration test rests on the experience of the test team. If some hacker has more experience than the test team I hire, I'm in trouble! So how do I even the odds? Instead of hiring a team to do a black box, in which they're going to spend hours searching for information and poking around, I give them the necessary information to test the network thoroughly, right up front. By doing so, their time is actually spent testing the network, not carrying out a high-tech scavenger hunt. Any good penetration test team is still going to do reconnaissance and tell me what information is available about my organization from public sources anyway. No, I'm not going to give up the administrative password to my network. But I am going to tell them what my IP ranges are, whether or not I have wireless, and whether I allow remote access into the network, among other things.

In addition to the types and variations of penetration testing, we also need to talk about announced and unannounced testing. Which of these two methods will be used depends on whether your intent is to test the network itself or the network's security staff. In an announced test, the penetration testing team works in "full cooperation" with the IT staff and the IT staff has "full knowledge" about the test, such as what will be tested and when. In an unannounced test, only specific members of the tested organization (usually the higher levels of management) are aware that the testing will take place. Even they may only know a "window" of time for testing, not the exact times or dates.

If you follow the published guidelines, an unannounced test is used when testing an organization's incident response capability is called for. Announced tests are used when the organization simply wants to test network devices. Is this really how it happens in the real world? Sometimes it isn't.

Most organizations that conduct annual testing do so at about the same time every year, especially if it's a government organization. So there's really no such thing as an "unannounced" test. Everyone knows that sometime between *X* and *Y* dates, they're going to be tested. In some organizations this means that during that timeframe there suddenly appears to be an increased awareness of network security. Machines get patched quicker. Logs are reviewed daily. Abnormal activities are reported immediately. After the testing window is over, however, it's back to the same old routine until the next testing window, next year.

What about announced testing, you ask? Think about it: If you're a network administrator and you know a test is coming, you're going to make sure that everything is as good as you can make it. Once again, there's that increased emphasis on security—until the testing window is over, that is.

Let's take a minute to recap what we've talked about so far. We've learned that a penetration test is used to exploit discovered vulnerabilities and to help determine what an attacker could do if they successfully exploited a vulnerability. We learned that not all vulnerabilities are actually a concern, because there might not be a way to exploit them or what we'd get by exploiting them wouldn't justify the time or effort we spent in doing so. We learned that there are different types and variations of penetration tests, that they can be announced or unannounced, and that none of them are actually "just like a hacker would do it." Probably the most important thing we've learned so far is that if we really and truly want to protect our network from a real-life attack, we have to offset the biggest advantage that a hacker has: time. We discovered that we can do this by giving the testing team sufficient information to thoroughly test the network instead of surfing the Internet on our dime. In today's penetration testing world , when we get hired to do a general penetration test, we inform the client that the level of skill we are going to emulate, shall be the skill set of an average hacker within the parameters set by the client. This means we will use a combination of tools and manual techniques and proven methodologies . Given the general scope of the assignment, this will not enable us to reverse engineer all of the applications and run debugging tools to find vulnerabilities, and write our own exploits, as it is too time consuming and obviously outside of the scope of the engagement.

5. PHASES OF PENETRATION TESTING

There are three phases in a penetration test, and they mimic the phases that an attacker would use to conduct a real attack. These phases are the pre-attack phase, the attack phase, and the post-attack phase, as shown in Figure 30.1.

The activities that take place in each phase (as far as the penetration testing team is concerned) depend on how the rules of engagement have specified that the penetration test be conducted. To give you a more complete picture, we talk about these phases from the perspective of a hacker and from that of a penetration team conducting the test under "black-box" conditions.

The Pre-Attack Phase

The pre-attack phase (see Figure 30.2) consists of the penetration team's or hacker's attempts to investigate or explore the potential target. This reconnaissance effort is

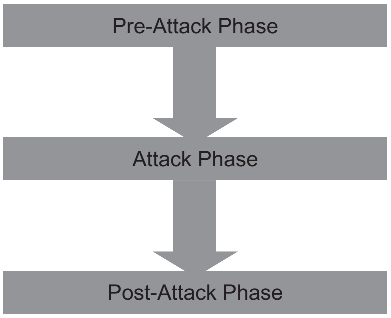

FIGURE 30.1 The three phases in a penetration test.

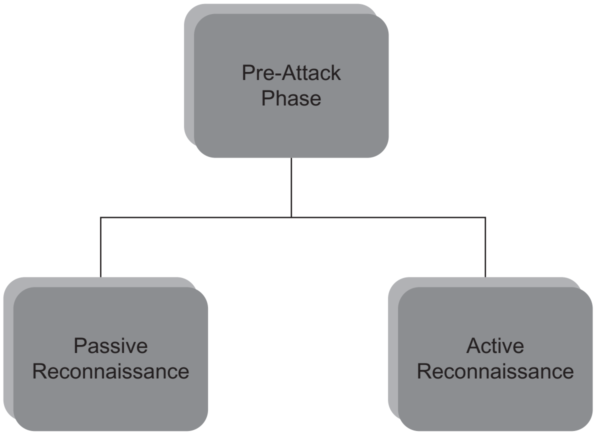

FIGURE 30.2 The pre-attack phase.

normally categorized into two types: active reconnaissance and passive reconnaissance.

Beginning with passive reconnaissance, which does not "touch" the network and is therefore undetectable by the target organization, the hacker or penetration tester will gather as much information as possible about the target company. Once all available sources for passive reconnaissance have been exhausted, the test team or attacker may move into active reconnaissance.

During active reconnaissance, the attacker may actually "touch" the network, thereby increasing the chance that they will be detected or alert the target that someone is "rattling the doorknobs." Some of the information gathered during reconnaissance can be used to produce a provisional map of the network infrastructure for planning a more coordinated attack strategy later. Ultimately it boils down to information gathering in all its many forms. Hackers will often spend more time on pre-attack or reconnaissance activities than on the actual attack itself.

The Attack Phase

This stage involves the actual compromise of the target. The hacker or test team may exploit a logical or physical vulnerability discovered during the pre-attack phase or use other methods such as a weak security policy to gain access to a system. The important point here is to understand that although there could be several possible vulnerabilities, the hacker needs only one to be successful to compromise the network.

By comparison, a penetration test team will be interested in finding and exploiting as many vulnerabilities as possible because neither the organization nor the test team will know which vulnerability a hacker will choose to exploit first (see Figure 30.3). Once inside, the attacker may attempt to escalate his or her privileges, install one or more applications to sustain their access, further exploit the compromised system, and/or attempt to extend their control to other systems within the network. When they've finished having their way with the system or network, they will attempt to eliminate all evidence of their presence in a process some call "covering their tracks."

The Post-Attack Phase

The post-attack phase is unique to the penetration test team. It revolves around returning any modified system(s) to the pretest state. With the exception of covering their tracks, a real attacker couldn't care less about returning a compromised system to its original state. The longer the system remains compromised, the longer they can legitimately claim credit for "pwning" (owning) the system.

Obviously, in a real penetration test, the following list would include reversal of each and every change made to the network to restore it to its pre-attack state. Some of the activities that the test team may have to accomplish are shown here:

- Removal of any files, tools, exploits, or other test-created objects uploaded to the system during testing
- Removal or reversal of any changes to the registry made during system testing
- Reversal of any access control list (ACL) changes to file(s) or folder(s) or other system or user object(s)
- Restoration of the system, network devices, and network infrastructure to the state the network was in prior to the beginning of the test

The key element for the penetration test team to be able to restore the network or system to its pre-attack state is documentation. The penetration testing team documents every step of every action taken during the test, for two reasons. The obvious one is so that they can reverse their steps to "cleanse" the system or network. The second reason is to ensure repeatability of the test. Why is repeatability an issue?

An important part of the penetration test team's job is not only to find and exploit vulnerabilities but also to recommend appropriate mitigation strategies for discovered

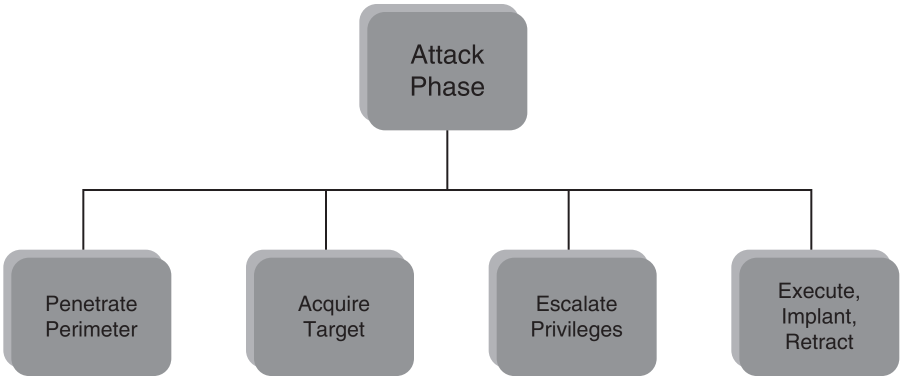

FIGURE 30.3 The attack phase.

vulnerabilities. This is especially true for those vulnerabilities that were successfully exploited. After the tested organization implements the recommended corrections, it should repeat the penetration test team's actions to ensure that the vulnerability has indeed been eliminated and that the applied mitigation has not had "unintended consequences" by creating a new vulnerability. The only way to do that is to recreate the original test that found the vulnerability in the first place, make sure it's gone, and then make sure there are no new vulnerabilities as a result of fixing the original problem.

As you might imagine, there are lots of possible ways for Murphy to stick his nose into the process we just talked about. How do penetration test teams and tested organizations try to keep Murphy at bay? Rules!

6. DEFINING WHAT'S EXPECTED

Someone once said: "You can't win the game if you don't know the rules!" That statement makes good sense for a penetration test team as well. Every penetration test must have a clearly defined set of rules by which the penetration test "game" is played. These rules are put into place to help protect both the tested organization and the penetration test team from errors of omission and commission (under normal circumstances). According to the National Institute of Standards and Technology (NIST), the "rule book" for penetration tests is often called the "Rules of Engagement." Rules of Engagement define things like which IP addresses or hosts are and are not allowed to be tested, which techniques are and are not allowed to be used, when testing is permitted or prohibited, points of contact for both the test team and the tested organization, IP addresses of machines from which testing is conducted, and measures to prevent escalation of an incident response to law enforcement, just to name a few.

There isn't a standard format for the Rules of Engagement, so it is not the only document that can be used to control a penetration test. Based on the complexity of the tested organization and the scope of the penetration test, the penetration test team may also use detailed test plan(s) for either or both logical and physical testing. In addition to these documents, both the client and the penetration test company conducting the operation will require some type of formal contact that spells out either explicitly, or incorporates by reference, such items as how discovered sensitive material will be handled, an indemnification statement, nondisclosure statement, fees, project schedule, reporting, and responsibilities. These are but a few of the many items that penetration testing control documents cover, but they should be sufficient for you to understand that all aspects of the penetration test need to be described somewhere in a document.

We now know what's expected during the penetration test. Armed with this information, how does the penetration test team plan to deliver the goods? It starts with a methodology.

7. THE NEED FOR A METHODOLOGY

When you leave for vacation and you've never been to your destination before, you're likely make a list of things you need or want to do before, during, or after the trip. You might also take a map along so you know how to get there and not get lost or sidetracked along the way. Penetration test teams also use a map of sorts. It's called their *methodology.*

A methodology is simply a way to ensure that a particular activity is conducted in a standard manner, with documented and repeatable results. It's a planning tool to help ensure that all mandatory aspects of an activity are performed.

Just as a map will show you various ways to get to your destination, a good penetration testing methodology does not restrict the test team to a single way of compromising the network. While on the road to your dream vacation, you might find your planned route closed or under construction and you might have to make a detour. You might want to do some sightseeing, or maybe visit long-lost relatives along the way.

Similarly, in a penetration test, your primary attack strategy might not work, forcing you to find a way around a particular network device, firewall, or intrusion prevention system. While exploiting one vulnerability, you may discover another one that leads you to a different host or a different subnet. A well-written methodology allows the test team the leeway necessary to explore these "targets of opportunity" while still ultimately guiding them to the stated goals of the test.

Most penetration test companies will have developed a standard methodology that covers all aspects of a penetration test. This baseline methodology document is the starting point for planning a particular test. Once the control documentation has been finalized, the penetration test team will know exactly what they can and cannot test. They will then modify that baseline methodology based on the scope statement in the Rules of Engagement for the penetration test that they are going to conduct.

Different clients are subject to different regulatory requirements such as HIPAA, Sarbanes-Oxley, Gramm-Leach-Bliley, or others, so the penetration test team's methodology must also be flexible enough to cover these and other government or private industry regulations.

In a minute, we'll talk about the sources of penetration testing methodologies, but for now, just understand that a methodology is not a "nice to have," it's a "must have." Without a methodology to be used as the basis to plan and execute a penetration test, there is no reliability. The team will be lost in the network, never knowing if they've fulfilled the requirements of the test or not until they're writing the report. By then, it's too late—for them and for the organization.

8. PENETRATION TESTING METHODOLOGIES

Back to our map example for a minute. Unless you're a cartographer, you're probably not going to make your own map to get to your dream vacation destination. You'll rely on a map that someone else has drawn, tested, and published. The same holds true for penetration testing methodologies. Before we talk about how a methodology, any methodology, is used in a penetration test, let's discuss penetration testing methodologies in general. There are probably as many different methodologies as there are companies conducting penetration tests, but all of them fit into one of two broad categories: open source or proprietary.

Open-source methodologies are just that: available for use by anyone. Probably the best-known open-source methodology, and de facto standard, is the Open Source Security Testing Methodology Manual (OSSTMM), the brainchild of Pete Herzog. You can get the latest copy of this document at www.isecom.org. Another valuable open-source methodology is the Open Web Application Security Project (OWASP), geared to securing Web applications, available at www.owasp.org.

Proprietary methodologies have been developed by particular entities offering network security services or certifications. The specific details of the processes that produce the output of the methodology are usually kept private. Companies wanting to use these proprietary methodologies must usually undergo specific training in their use and abide by quality standards set by the methodology proponent. Some examples of proprietary methodologies include IBM, ISS, Foundstone, and our own EC Council Licensed Penetrator Tester methodology.

9. METHODOLOGY IN ACTION

A comprehensive penetration test is a systematic analysis of all security controls in place at the tested organization. The penetration test team will look at not only the logical and physical vulnerabilities that are present but also at the tested organization's policies and procedures to assess whether or not the controls in place adequately protect the organization's information infrastructure.

Let's examine the use of a penetration testing methodology in more detail to demonstrate how it's used to conduct a penetration test. Of course, as the President of the EC-Council, I'm going to take the liberty of using our LPT methodology as the example.

EC-Council LPT Methodology

Figure 30.4 is a block representation of some of the major areas of the LPT methodology as taught in the EC-Council's Licensed Penetration Tester certification course. The first two rows of the diagram (except for the Wireless Network Penetration Testing block) represent a fairly normal sequence of events in the conduct of a penetration test. The test team will normally start by gathering information, then proceed with vulnerability discovery and analysis, followed by penetration testing from the network perimeter, and graduating to the internal network.

After that, beginning with wireless testing, what the test team actually does will depend on what applications or services are present in the network and what is allowed to be tested under the Rules of Engagement. I've chosen not to show every specific step in the process as part of the diagram. After all, if I told you everything, there wouldn't be any reason for you to get certified as a Licensed Penetration Tester, would there?

The methodology (and course) assumes that the penetration test team has been given authorization to conduct a complete test of the target network, including using denial-of-service tactics so that we can acquaint our LPT

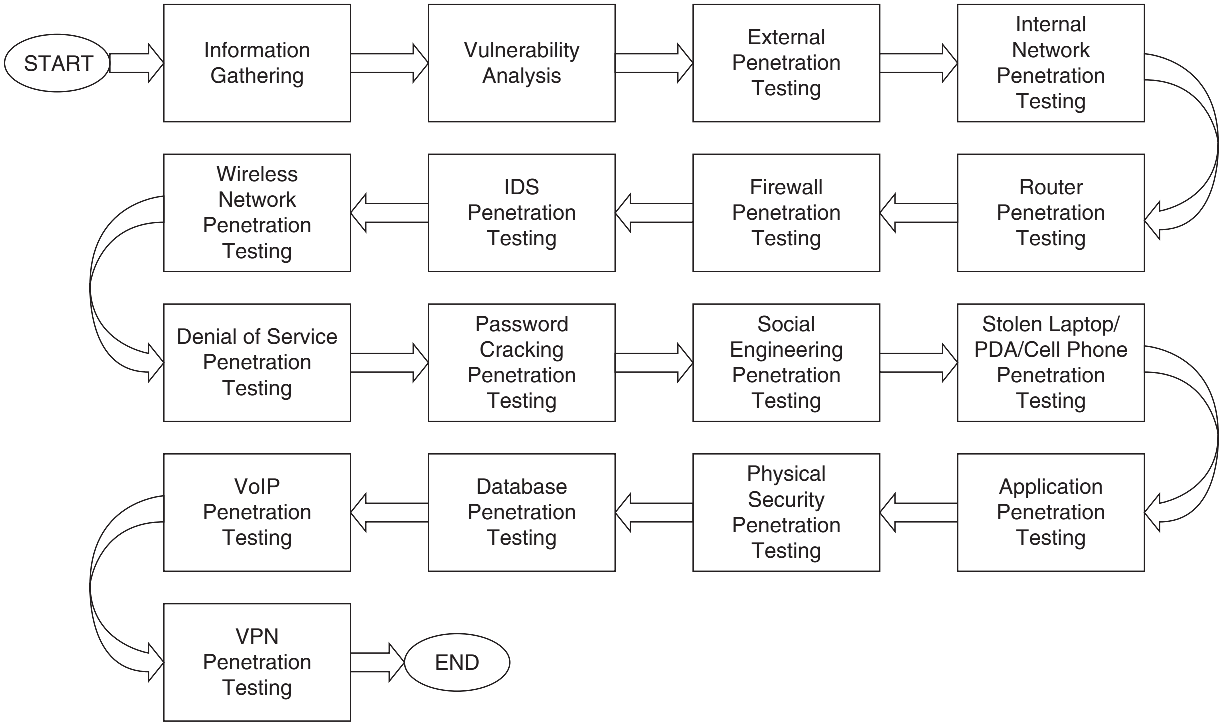

FIGURE 30.4 Block representation of some of the major areas of the LPT methodology.

candidates with the breadth of testing they may be called on to perform. In real life, a test team may seldom actually perform DoS testing, but members of the penetration test team must still be proficient in conducting this type of test, to make recommendations in their reports as to the possible consequences of an attacker conducting a DoS attack on the company's network infrastructure. Here I give you a quick overview of each of the components.

Information Gathering

The main purpose of information gathering is to understand more about the target company. As we've already talked about, there are a number of ways to gather information about the company from public domain sources such as the Internet, newspapers, and third-party information sources.

Vulnerability Analysis

Before you can attack, you have to find the weak points. A vulnerability analysis is the process of identifying logical weaknesses in computers and networks as well as physical weaknesses and weaknesses in policies, procedures, and practices relating to the network and the organization.

External Penetration Testing

External testing is normally conducted before internal testing. It exploits discovered vulnerabilities that are accessible from the Internet to help determine the degree of information exposure or network control that could be achieved by the successful exploitation of a particular vulnerability from outside the network.

Internal Network Penetration Testing

Internal testing is normally conducted after external testing. It exploits discovered vulnerabilities that are accessible from inside the organization to help determine the degree of information exposure or network control that could be achieved by the successful exploitation of a particular vulnerability from inside the network.

Router Penetration Testing

Depending on where they are located in the network infrastructure, routers may forward data to points inside or outside the target organization's network. Take down a router; take down all hosts connected to that router. Because of their importance, routers that connect the target organization to the Internet may be tested twice: once from the Internet and again from inside the network.

Firewall Penetration Testing

Firewall(s) are another critical network infrastructure component that may be tested multiple times, depending on where they reside in the infrastructure. Firewalls that are exposed to the Internet are a primary line of defense for the tested organization and so will usually be tested from the Internet and from within the DMZ for both ingress and egress vulnerabilities and proper rule sets. Internal firewalls are often used to segregate portions of the internal network from each other. Those firewalls are also tested from both sides and for ingress and egress filtering to ensure that only applicable traffic can be passed.

IDS Penetration Testing

As networks have grown more complex and the methods to attack them have multiplied, more and more organizations have come to rely on intrusion detection (and prevention) systems (IDS/IPS) to give them warning or prevent an intrusion from occurring. The test team will be extremely interested in testing these devices for any vulnerabilities that will allow an attacker to circumvent setting of the IPS/IDS alarms.

Wireless Network Penetration Testing

If the target company uses wireless (and who doesn't these days), the test team will focus on the availability of "outside" wireless networks that can be accessed by employees of the target company (effectively circumventing the company's firewalls), the "reach" of the company's own wireless signal outside the physical confines of the company's buildings, and the type and strength of encryption employed by the wireless network. With the explosion of smart phones this has expanded significantly, and requires much time and consideration in the testing methodology if an organization is syncing their smart phones, or more importantly using a Blackberry Enterprise Server (BES), one of our Master Trainers while doing a penetration test for a large financial organization was able to compromise the BES and this machine holds all of the files from the Blackberry device, over the years the Blackberry has made improvements in their security, but when an organization deploys a BES then they have accepted the risk that if that gets a vulnerability and is compromised then all of the data that is stored on ALL of the organizations Blackberry devices is compromised, think about that, what do you have on your Blackberry today? It is not only Blackberry, but all of the smart phones carry with them similar risks, not to mention each and every application on the device is susceptible to the same vulnerabilities as our systems have been for years. There is a saying " Hack the iPhone, there is an app for that."

Denial-of-Service Penetration Testing

If the test team is lucky enough to land a penetration test that includes DoS testing, they will focus on crashing the company's Web sites and flooding the sites or the internal network with enough traffic to bring normal business processes to a standstill or a crawl. They may also attempt to cause a DoS by locking out user accounts instead of trying to crack the passwords.

Password-Cracking Penetration Testing

Need we say more?

Social Engineering Penetration Testing

The test team may use both computer- and human-based techniques to try to obtain not only sensitive and/or nonpublic information directly from employees but also to gain unescorted access to areas of the company that are normally off-limits to the public. Once alone in an off-limits area, the social engineer may then try to obtain additional sensitive or nonpublic information about the company, its data, or its customers. This has taken on a whole new level, whereas before the most common method was by phone, we now have all the email attacks, and the variants that have proven largely successful, and now with the advent of social networking by the vast majority of the online population the attack surface for this has no boundaries, and it is not just Facebook and Twitter, it is the combination of these different profiles that can be used to social engineer information from perspective victims.

Stolen Laptop, PDA, and Cell Phone Penetration Testing

Some organizations take great pains to secure the equipment that is located within the physical confines of their buildings but fail to have adequate policies and procedures in place to maintain that security when mobile equipment leaves the premises. The test team attempts to temporarily "liberate" mobile equipment and then conducts testing to gain access to the data stored on those devices. They will most often attempt to target either or both members of the IT Department and the senior members of an organization in the hopes that their mobile devices will contain the most useful data.

Application Penetration Testing

The test team will perform meticulous testing of an application to check for code-related or "back-end" vulnerabilities that might allow access to the application itself, the underlying operating system, or the data that the application can access.

Physical Security Penetration Testing

The test team may attempt to gain access to the organizational facilities before, during, or after business hours using techniques meant to defeat physical access control systems or alarms. They may also conduct an overt "walk-thorough" accompanied by a member of the tested organization to provide the tested company with an "objective perspective" of the physical security controls in place. Either as a part of physical security testing or as a part of social engineering, the team may rifle through the organization's refuse to discover what discarded information could be used by an attacker to compromise the organization and to observe employee reaction to an unknown individual going through the trash.

Database Penetration Testing

The test team may attempt to directly access data contained in the database using account password-cracking techniques or indirectly access data by manipulating triggers and stored procedures that are executed by the database engine.

Voice-Over-IP Penetration Testing

The test team may attempt to gain access to the VoIP network for the purpose of recording conversations or to perform a DoS to the company's voice communications network. In some cases, if the organization has not followed the established "best practices" for VoIP, the team may attempt to use the VoIP network as a jumping-off point to conduct further compromise of the organization's network backbone.

VPN Penetration Testing

A number of companies allow at least some of their employees to work remotely, either from home or while they are "on the road." In either case, a VPN represents a trusted connection to the internal network. The test team will attempt to gain access to the VPN by either compromising the remote endpoint or gaining access to the VPN tunnel so that they have a "blessed" connection to the internal company network.

In addition to testing the applicable items in the blocks on the previous diagram, the penetration test team must also be familiar with and able to test for compliance with the regulatory requirements to which the tested organization is subject. Each standard has specific areas that must be tested, the process and procedures of which may not be part of a standard penetration test.

I'm sure that as you read the previous paragraphs, there was a nagging thought in the back of your mind: What are the risks involved? Let's talk about the risks.

10. PENETRATION TESTING RISKS

The difference between a real attack and a penetration test is the penetration tester's intent, authority to conduct the test, and lack of malice. Because penetration testers may use the same tools and procedures as a real attacker, it should be obvious that penetration testing can have serious repercussions if it's not performed correctly.

Even if your target company ceased all operations for the time the penetration test was being conducted, there is still a danger of data loss, corruption, or system crashes that might require a reinstall from "bare metal." Few, if any, companies can afford to stop functioning while a penetration test is being performed. Therefore it is incumbent on both the target organization and the penetration test team to do everything in their power to prevent an interruption of normal business processes during penetration testing operations.

Target companies should be urged to back up all their critical data before testing begins. They should always have IT personnel present to immediately begin restoration in the unfortunate event that a system crashes or otherwise becomes unavailable. The test team must be prepared to lend all possible assistance to the target company in helping to restore any system that is affected by penetration testing activities.

11. LIABILITY ISSUES

Although we just discussed some of the risks involved with conducting a penetration test, the issue of liability deserves its own special section. A botched penetration test can mean serious liability for the penetration test company that conducted the testing. The penetration test company should ensure that the documentation for the penetration test includes a liability waiver.

The waiver must be signed by an authorized representative of the target company and state that the penetration testing firm cannot be held responsible for the consequences of items such as:

- Damage to systems
- Unintentional denial-of-service conditions
- Data corruption
- System crashes or unavailability
- Loss of business income

12. LEGAL CONSEQUENCES

The legal consequences of a penetration test gone wrong can be devastating to both the target company and the penetration testers performing the test. The company may become the target of lawsuits by customers. The penetration testers may become the target of lawsuits by the target company. The only winners in this situation are the

lawyers. It is imperative that proper written permission is obtained from the target company before *any* testing is conducted.

Legal remedies are normally contained in a penetration testing contract that is drawn up in addition to the testing control documentation. Both the penetration test company and the target company should seek legal counsel to review the agreement and to protect their interests. The authorization to perform testing must come from a senior member of the test company, and that senior member must be someone who has the authority to authorize such testing, not just the network administrator or LAN manager.

Authorized representatives of both the penetration test company and the target company must sign the penetration testing contract to indicate that they agree with its contents and the contents of all documentation that may be included or included by reference, such as the Rules of Engagement, the test plan, and other test control documentation.

13. "GET OUT OF JAIL FREE" CARD

We just talked about how the target company and the penetration test company protect themselves. What about that individual team member crawling around in the dumpster at 2:00 A.M., or the unfortunate team member who's managed to get into the company president's office and log onto his or her computer? What protection do those individuals have when that 600-pound gorilla of a security guard clamps his hand on their shoulder and asks what they're doing?

A "Get Out of Jail Free" card might just work wonders in these and other cases. Though not really a card, it's usually requested by the penetration test team as "extra insurance" during testing. It is presented if they're detained or apprehended while in the performance of their duties, as proof that their actions are sanctioned by the officers of the company. The card may actually be a letter on the tested company's letterhead and signed by the senior officer authorizing the test. It states the specific tasks that can be performed under the protection of the letter and specifically names the bearer.

It contains language that the bearer is conducting activities and testing under the auspices of a contract and that no violation of policy or crime is or has been committed. It includes a 24-hour contact number to verify the validity of the letter. As you can imagine, these "Get Out of Jail Free" cards are *very* sensitive and are usually distributed to team members immediately before testing begins, collected, and returned to the target company immediately after the end of any testing requiring their use.

There is a tremendous amount of work involved in conducting a thorough and comprehensive penetration test. What we've just discussed is but a 40,000-foot flyover of what actually happens during the process. But we're not done yet! The one area that we haven't discussed is the personnel performing these tests.

14. PENETRATION TESTING CONSULTANTS

The quality of the penetration test performed for a client is directly dependent on the quality of the consultants performing the work, singularly and in the aggregate. There are hundreds if not thousands of self-proclaimed "security services providers" out there, both companies and individuals. If I'm in need of a penetration test, how can I possibly know whether the firm or individual I'm going to select is really and truly qualified to test my network comprehensively, accurately, and safely? What if I end up hiring a consultancy that employs hackers? What if the consultant(s) aren't hackers, but they just don't know what they're doing?

In these, the last pages of this chapter, I want to talk about the people who perform penetration testing services. First, you get another dose of my personal opinion. Then we'll talk about security services providers, those who provide penetration testing services. We'll talk about some of the questions that you might want to ask about their operations and their employees. Here's a hint for you: If the company is evasive in answering the questions or outright refuses to answer them—run!

What determines whether or not a penetration tester is "experienced"? There are few benchmarks to test the knowledge of a penetration tester. You can't ask her for a score: "Yes, I've performed 27 penetration tests, been successful in compromising 23 of those networks, and the overall degree of difficulty of each one of those tests was 7 on a scale of 1 to 10."

There really isn't a Better Business Bureau for penetration testers. You can't go to a Web site and see that XSecurity has had three complaints filed against them for crashing networks they've been testing or that "John Smith" has tested nine networks that were hacked within the following 24 hours. (Whoa! What an idea ... ! Nah, wouldn't work.) Few companies would want to admit that they chose the wrong person or company to test their networks, and that kind of information would surely be used by attackers in the "intelligence-gathering phase" as a source of information for future attacks on any company that chose to report. Well, if we can't do that, what can we do?

We pretty much have to rely on "word of mouth" that such-and-such a company does a good job. We have to pretty much rely on the fact that the tester has been

An Agenda for Action for the Experiences of the Test Team

The checklist that follows should give you some indication of questions you can ask to determine the "experiences" of your test team (check all tasks completed):

_____**1.** Have they conducted research and development in the security arena?
_____**2.** Have they published research papers or articles in technical journals?
_____**3.** Have they presented at seminars, either locally or internationally?
_____**4.** What certifications do they hold?
_____**5.** Where are those certifications from?
_____**6.** Do they maintain membership/affiliation/ accreditation in organizations such as the EC-Council, ISC2, ISACA, and others?
_____**7.** Have they written or contributed to security-related books and articles?
_____**8.** How about some simple questions to ask of the company that will perform your test?

certified to a basic standard of knowledge by a reputable certification body. We pretty much have to rely on the skill set of the individual penetration tester and that "the whole is more than the sum of its parts" thing called synergy, which is created when a group of penetration testers works together as a team.

I'm not going to insult you by telling you how to go ask for recommendations. I will tell you that there are security certification providers who are better than others and who hold their candidates to a higher standard of knowledge and professionalism than others. Since it's hard to measure the "synergy" angle, let's take a closer look at what skill sets should be present on the penetration team that you hire.

15. REQUIRED SKILL SETS

Your penetration test "dream team" should be well versed in areas such as these:

- Networking concepts
- Hardware devices such as routers, firewalls, and IDS/IPS
- Hacking techniques (ethical hacking, of course!)
- Databases
- Open-source technologies
- Operating systems
- Wireless protocols
- Applications
- Protocols
- Many others

That's a rather long list to demonstrate a simple concept: Your penetration team should be able to show proof that they have knowledge about all the hardware, software, services, and protocols in use within your network.

Okay. They have technical skills. Is that enough?

16. ACCOMPLISHMENTS

Are the members of the test team "bookworms" or have they had practical experience in their areas of expertise? Have they contributed to the security community (see checklist: "An Agenda For Action For The Experiences Of The Test Team")?

17. HIRING A PENETRATION TESTER

Here are some of the questions you might consider asking prospective security service providers or things to think about when hiring a test team:

- Is providing security services the primary mission of the security service provider, or is this just an "additional revenue source" for another company?
- Does the company offer a comprehensive suite of services tailored to your specific requirements, or do they just offer service packages?
- Does the supplier have a methodology? Does their methodology follow a recognized authority in security such as OSSTMM, OWASP, or LPT?
- Does the supplier hire former hackers? Do they perform background checks on their employees?
- Can they distinguish (and articulate) between infrastructure and application testing?
- How many consultants does the supplier have who perform penetration testing? How long have those consultants been practicing?
- What will the final report look like? Does it meet your needs? Is the supplier willing to modify the format to suit your needs (within reason)?
- Is the report just a list of what's wrong, or does it contain mitigation strategies that will be tailored to your particular situation?
- Is the supplier a recognized contributor to the security community?
- Do they have references available to attest to the quality of work already performed?
- That ought to get a company started down the road to hiring a good penetration test team. Now let's talk about why a company should hire you, either as an individual or as a member of a penetration testing team.

18. WHY SHOULD A COMPANY HIRE YOU?

When a prospective client needs a penetration test, they may publish a request for proposal (RFP) or just make an announcement that they are accepting solicitations for security services. When all the bids come in, they will only consider the most qualified candidates. How to you make sure that your or your company's bid doesn't end up in the "circular file?"

Qualifications

Highlight your or your company's qualifications to perform the desired services. Don't rely on "alphabet soup" after your name or your team's names to highlight qualifications. Take the time to explain the meaning of CISSP, LPT, or MCSE.

Work Experience

The company will provide some information about itself. Align your response by highlighting work (without naming specific clients!) in the same or related fields and of related size.

Cutting-Edge Technical Skills

It doesn't bode well when you list one of your primary skills as "MCSE in Windows NT 3.51 and NT 4.0 or higher." Maintain your technical proficiency and showcase your most recent and most highly regarded certification accomplishments, such as CCNA, CEH, CHFI, CCNP, MCSE, LPT, CISA, and CISM.

Communication Skills

Whether your communicate with the prospective client through written or verbal methods, made sure you are well written or well spoken. Spell-check your written documents, and then look them over again. There are some errors that spell checkers just won't find. "Dude, I'm gonna hack yer network!" isn't going to cut it in a second-round presentation.

Attitude

Let's face it: Most of us in the security arena have a bit of an ego and sometimes come off as a bit arrogant. Though that may hold some sway with your peers, it won't help your case with a prospective client. Polite and professional at all times is the rule.

Team Skills

There is no synergy if there is no team. You must be a good team player who can deal with subordinates, superiors, and clients professionally, even in the most critical moments of an engagement.

Okay. You've done all this. What else do you need to know to get hired? What about the concerns of the company that will hire you?

Company Concerns

You can have a sterling record and the best qualifications around and still not get hired. Here are some of the "influencing factors" companies may consider when looking to hire a penetration testing team:

- Companies usually want to work in collaboration with reputable and well-established firms such as Foundstone, ISS, EC-Council, and others.
- Companies may want to verify the tools that will be run during a test and the equipment on which the tools run.
- Companies will want references for the individuals on the team as well as recommendations about the company itself.
- Companies demand security-related certifications such as CISSP, CEH, and TICSA to confirm the authenticity of the testing company.
- Companies usually have an aversion to hiring those who are known or suspected hackers.
- Companies may require security clearances.
- Companies may inquire about how and where their data will be stored while in the testing company's possession.

Okay, you get the idea, right?

19. SUMMARY

Anybody got an aspirin? I'm sure you probably need one after reading all the information I've tried to throw at you in this chapter. I've only barely scratched the surface of what a penetration test is, what it's meant to accomplish, how it's done, and how you report the findings to the client, but I'm out of space to tell you more.

Let me take these last couple of inches on the page to summarize. If you've got a network, the question is not "if you'll be attacked, but "when." If you're going to make your network as safe as possible, you need to find the weaknesses and then test them to see which ones are really, truly the things that need to be fixed "yesterday." If you only conduct a penetration test once a year, a real hacker has 364 "unbirthdays" in which to attack and compromise your network. Don't give them the opportunity.

Get someone on your staff certified as an ethical hacker and a Licensed Penetration Tester so that they can perform ethical hacks and penetrations on a regular basis to help protect your network.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Penetration testing is the exploitation of vulnerabilities absent in an organization's network.
2. True or False? Some sources classify penetration testing into two types—internal and external—and then talk about the "variations" of these types of tests based on the amount of information the test team has been given about the organization prior to starting the test.
3. True or False? When a penetration test is conducted against Internet-facing hosts, it is known as *external testing*.
4. True or False? There are three phases in a penetration test, and they mimic the phases that an attacker would use to conduct a real attack.
5. True or False? The pre-attack phase consists of the penetration team's or hacker's attempts to investigate or explore the potential target.

Multiple Choice

1. What stage involves the actual compromise of the target?
   A. Worm Phase
   B. Virus Phase
   C. Backdoor Phase
   D. More popular Phase
   E. Attack Phase
2. What is unique to the penetration test team?
   A. Backdoor Phase
   B. Virus Phase
   C. Post-Attack Phase
   D. Packet filter Phase
   E. User-level Rootkit Phase
3. What is simply a way to ensure that a particular activity is conducted in a standard manner, with documented and repeatable results?
   A. Stateful firewalls
   B. Virus
   C. Methodology
   D. Backdoor
   E. User-level Rootkit
4. What have been developed by particular entities offering network security services or certifications?
   A. Application layer firewalls
   B. Proprietary methodologies
   C. Worms
   D. Backdoors
   E. User-level Rootkit
5. What test is a systematic analysis of all security controls in place at the tested organization?
   A. Trojan Horse
   B. Firewalls
   C. Worm
   D. Comprehensive penetration
   E. User-level Rootkit

EXERCISE

Problem

Penetration testing can also be useful for determining?

Hands-On Projects

Project

The discovery phase of penetration testing includes two parts. The first part is the start of actual testing, and covers information gathering and scanning. Network port and service identification is conducted to identify potential targets. In addition to port and service identification, what other techniques are used to gather information on the targeted network?

Case Projects

Problem

While vulnerability scanners check only for the possible existence of a vulnerability, the attack phase of a penetration test exploits the vulnerability to confirm its existence. Most vulnerabilities exploited by penetration testing fall into which of the following categories?

Optional Team Case Project

Problem

Identify some penetration testing logistics.

Chapter 31

What is Vulnerability Assessment?

Almantas Kakareka
Demyo, Inc.

1. INTRODUCTION

In computer security, the term *vulnerability* is applied to a weakness in a system that allows an attacker to violate the integrity of that system. Vulnerabilities may result from weak passwords, software bugs, a computer virus or other malware (malicious software), a script code injection, or from unchecked user input, just to name a few.

A security risk is classified as vulnerability if it is recognized as a possible means of attack. A security risk with one or more known instances of a working or fully implemented attack is classified as an *exploit*. Constructs in programming languages that are difficult to use properly can be large sources of vulnerabilities.

Vulnerabilities always existed, but when the Internet was in its early stage they were not as often used and exploited. The media did not report news of hackers who were getting put in jail for hacking into servers and stealing vital information.

Vulnerability assessment may be performed on many objects, not only computer systems/networks. For example, a physical building can be assessed so it will be clear what parts of the building have what kind of flaw. If the attacker can bypass the security guard at the front door and get into the building via a back door, it is definitely vulnerability. Actually, going through the back door and using that vulnerability is called an *exploit*. The physical security is one of the most important aspects to be taken into account. If the attackers have physical access to the server, the server is not yours anymore! Just stating, "Your system or network is vulnerable" doesn't provide any useful information. Vulnerability assessment without a comprehensive report is pretty much useless. A vulnerability assessment report should include:

- Identification of vulnerabilities
- Risk rating of each vulnerability (Critical, High, Medium, Low)
- Quantity of vulnerabilities

It is enough to find one critical vulnerability, which means the whole network is at risk, as shown in Figure 31.1.

FIGURE 31.1 One critical vulnerability affects the entire network.

Vulnerabilities should be sorted by severity and then by servers/services. Critical vulnerabilities should be at the top of the report and should be listed in descending order, that is, critical, then high, medium, and low.

2. REPORTING

Reporting capability is of growing importance to administrators in a documentation-oriented business climate where you must not only be able to do your job, you must also provide written proof of how you've done it. In fact, respondents to Sunbelt's survey[1] indicate that flexible and prioritizing reporting is their number-one favorite feature.

A scan might return hundreds or thousands of results, but the data is useless unless it is organized in a way that can be understood. That means that ideally you will be able to sort and cross-reference the data, export it to other programs and formats (such as CSV, HTML, XML, MHT, MDB, Excel, Word, and/or various databases), view it in different ways, and easily compare it to the results of earlier scans.

Comprehensive, flexible, and customizable reporting is used within your department to provide a guideline of technical steps you need to take, but that's not all. Good reports also give you the ammunition you need to justify to management the costs of implementing security measures.

1. "Vulnerability Assessment Scanning:Why Sunbelt Network Security Inspector (SNSI)?" Sunbelt Software, [http://img2.insight.com/graphics/uk/content/microsite/sunbelt/sunbelt_network_security_inspector_white-paper.pdf], February 2004.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00031-3

3. THE "IT WON'T HAPPEN TO US" FACTOR

Practical matters aside, CEOs, CIOs, and administrators are all human beings and thus subject to normal human tendencies—including the tendency to assume that bad things happen to "other people," not to us. Organizational decision makers assume that their companies aren't likely targets for hackers ("Why would an attacker want to break into the network of Widgets, Inc., when they could go after the Department of Defense or Microsoft or someone else who's much more interesting?").[1]

4. WHY VULNERABILITY ASSESSMENT?

Organizations have a tremendous opportunity to use information technologies to increase their productivity. Securing information and communications systems will be a necessary factor in taking advantage of all this increased connectivity, speed, and information. However, no security measure will guarantee a risk-free environment in which to operate. In fact, many organizations need to provide easier user access to portions of their information systems, thereby increasing potential exposure. Administrative error, for example, is a primary cause of vulnerabilities that can be exploited by a novice hacker, whether an outsider or insider in the organization. Routine use of vulnerability assessment tools along with immediate response to identified problems will alleviate this risk. It follows, therefore, that routine vulnerability assessment should be a standard element of every organization's security policy. Vulnerability assessment is used to find unknown problems in the systems. The main purpose of vulnerability assessment is to find out what systems have flaws and take action to mitigate the risk. Some industry standards such as DSS PCI require organizations to perform vulnerability assessments on their networks. The sidebar "DSS PCI Compliance" gives a brief look.

DSS PCI Compliance

PCI DSS stands for Payment Card Industry Data Security Standard. This standard was developed by leading credit-card companies to help merchants be secure and follow common security criteria to protect sensitive customers' credit-card data. Before that every credit card company had a similar standard to protect customer data on the merchant side. Any company that does transactions via credit cards needs to be PCI compliant. One of the requirements to be PCI compliant is to regularly test security systems and processes. This can be achieved via vulnerability assessment. Small companies that don't process a lot of transactions are allowed to do self-assessment via questionnaire. Big companies that process a lot of transactions are required to be audited by third parties.[2]

5. PENETRATION TESTING VERSUS VULNERABILITY ASSESSMENT

There seems to be a certain amount of confusion within the security industry about the difference between penetration testing and vulnerability assessment. They are often classified as the same thing but in fact they are not. Penetration testing sounds a lot more exciting, but most people actually want a vulnerability assessment and not a penetration test, so many projects are labeled as penetration tests when in fact they are 100% vulnerability assessments.

A penetration test mainly consists of a vulnerability assessment, but it goes one step further. A penetration test is a method for evaluating the security of a computer system or network by simulating an attack by a malicious hacker. The process involves an active analysis of the system for any weaknesses, technical flaws, or vulnerabilities. This analysis is carried out from the position of a potential attacker and will involve active exploitation of security vulnerabilities. Any security issues that are found will be presented to the system owner, together with an assessment of their impact and often with a proposal for mitigation or a technical solution.

A vulnerability assessment is what most companies generally do, since the systems they are testing are live production systems and can't afford to be disrupted by active exploits that might crash the system. Vulnerability assessment is the process of identifying and quantifying vulnerabilities in a system. The system being studied could be a physical facility such as a nuclear power plant, a computer system, or a larger system (for example, the communications infrastructure or water infrastructure of a region). Vulnerability assessment has many things in common with risk assessment. Assessments are typically performed according to the following steps:

1. Cataloging assets and capabilities (resources) in a system
2. Assigning quantifiable value and importance to the resources
3. Identifying the vulnerabilities or potential threats to each resource
4. Mitigating or eliminating the most serious vulnerabilities for the most valuable resources

This is generally what a security company is contracted to do, from a technical perspective—not to actually penetrate the systems but to assess and document the

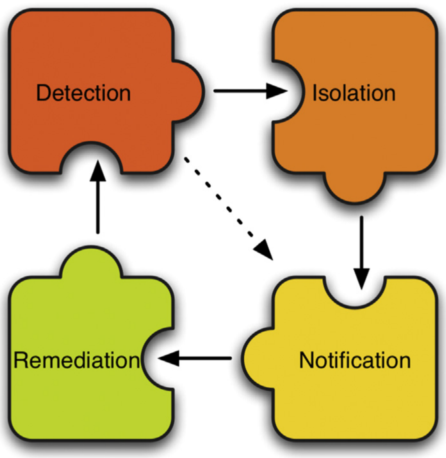

FIGURE 31.2 Vulnerability mitigation cycle.

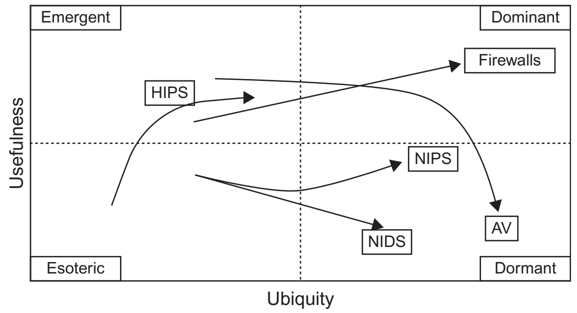

FIGURE 31.3 Usefulness/ubiquity relationship.

possible vulnerabilities and to recommend mitigation measures and improvements. Vulnerability detection, mitigation, notification, and remediation are linked, as shown in Figure 31.2.[3]

6. VULNERABILITY ASSESSMENT GOAL

The theoretical goal of network scanning is elevated security on all systems or establishing a network-wide minimal operation standard. Figure 31.3 shows how usefulness is related to ubiquity:

- HIPS: Host-Based Intrusion Prevention System
- NIDS: Network-Based Intrusion Detection System
- AV: Antivirus
- NIPS: Network-Based Intrusion Prevention System

7. MAPPING THE NETWORK

Before we start scanning the network we have to find out what machines are alive on it. Most of the scanners have a built-in network mapping tool, usually the Nmap network mapping tool running behind the scenes. The Nmap Security Scanner is a free and open-source utility used by millions of people for network discovery, administration, inventory, and security auditing. Nmap uses raw IP packets in novel ways to determine what hosts are available on a network, what services (application name and version) those hosts are offering, what operating systems they are running, what type of packet filters or firewalls are in use, and more. Nmap was named "Information Security Product of the Year" by *Linux Journal* and *Info World*. It was also used by hackers in the movies *Matrix Reloaded, Die Hard* 4, and *Bourne Ultimatum*. Nmap runs on all major computer operating systems, plus the Amiga. Nmap has a traditional command-line interface, as shown in Figure 31.4; and, zenmap is the official nmap security scanner GUI (see Figure 31.5).

It is a multiplatform (Linux, Windows, Mac OS X, BSD, etc.), free and open-source application that aims to make Nmap easy for beginners to use while providing advanced features for experienced Nmap users. Frequently used scans can be saved as profiles to make them easy to run repeatedly. A command creator allows interactive creation of Nmap command lines. Scan results can be saved and viewed later. Saved scan results can be compared with one another to see how they differ. The results of recent scans are stored in a searchable database.

Gordon Lyon (better known by his nickname, Fyodor) released Nmap in 1997 and continues to coordinate its development. He also maintains the Insecure.Org, Nmap.Org, SecLists.Org, and SecTools.Org security resource sites and has written seminal papers on OS detection and stealth port scanning. He is a founding member of the Honeynet project and coauthored the books *Know Your Enemy: Honeynets* and *Stealing the Network: How to Own a Continent*. Gordon is President of Computer Professionals for Social Responsibility (CPSR), which has promoted free speech, security, and privacy since 1981.[4]

Some systems might be disconnected from the network. Obviously, if the system is not connected to any network at all it will have a lower priority for scanning. However, it shouldn't be left in the dark and not be scanned at all, because there might be other nonnetwork related flaws, for example, a Firewire exploit that can be used to unlock the Windows XP SP2 system. Exploits work like this: An attacker approaches a locked Windows XP SP2 station, plugs a Firewire cable into it, and uses special commands to unlock the locked machine. This technique is possible because Firewire has direct access

to RAM. The system will accept any password and unlock the computer.[5]

8. SELECTING THE RIGHT SCANNERS

Scanners alone don't solve the problem; using scanners well helps solve *part* of the problem. Start with one scanner but consider more than one. It is a good practice to use more than one scanner. This way you can compare results from a couple of them. Some scanners are more focused on particular services. Typical scanner architecture is shown in Figure 31.6.

For example, Nessus is an outstanding general-purpose scanner, but Web application-oriented scanners such as HP Web Inspect or Hailstorm will do a much better job of scanning a web application. In an ideal situation, scanners would not be needed because everyone would maintain patches and tested hosts, routers, gateways, workstations, and servers. However, the real world is different; we are humans and we tend to forget to install updates, patch systems, and/or configure systems properly. Malicious code will always find a way into your network! If a system is connected to the network, that means there is a possibility that this system will be infected at some time in the future. The chances might be higher or lower depending on the system's maintenance level. The system will never be secure 100%. There is no such thing as 100% security; if well maintained, it might be 99.9999999999% secure, but never 100%. There is a joke that says, if you want to make a computer secure, you have to disconnect it from the network and power outlet and then put it into a safe and lock it. This system will be *almost* 100% secure (although not useful), because social engineering cons may call your employees and ask

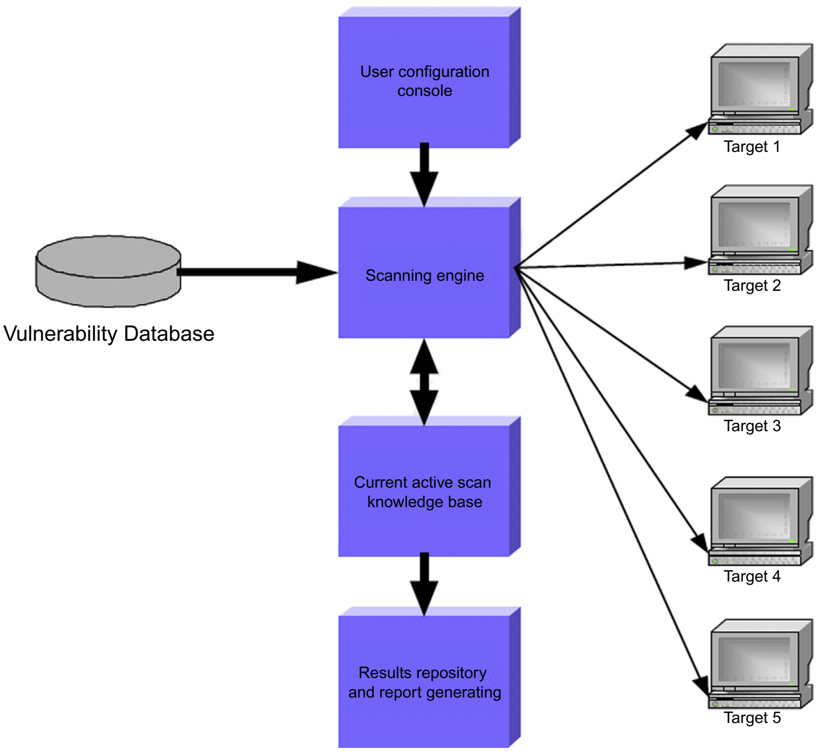

FIGURE 31.6 Typical scanner architecture.

them to remove that system from the safe and plug it back into the network.[6,7]

9. CENTRAL SCANS VERSUS LOCAL SCANS

The question arises: Should we scan locally or centrally? Should we scan the whole network at once, or should we scan the network based on subdomains and virtual LANs? Table 31.1 shows pros and cons of each method.

With localized scanning and central scanning verification, central scanning becomes a verification audit. The question again arises, should we scan locally or centrally? The answer is both. Central scans give overall visibility into the network. Local scans may have higher visibility into the local network. Centrally driven scans serve as the baseline. Locally driven scans are key to vulnerability reduction. Scanning tools should support both methodologies. Scan managers should be empowered to police their own area and enforce policy. So what will hackers target? Script kiddies will target any easily exploitable system; dedicated hackers will target some particular network/organization (see sidebar, "Who Is the Target?").

TABLE 31.1 Pros and Cons of Central Scans and Local Scans.

	Centrally Controlled and Accessed Scanning	Decentralized Scanning
Pros	Easy to maintain	Scan managers can scan at will
Cons	Slow; most scans must be queued	Patching of the scanner is often overlooked

Who is the Target?

"We are not a target." How many times have you heard this statement? Many people think that they don't have anything to hide, they don't have secrets, and thus nobody will hack them. Hackers are not only after secrets but after resources as well. They may want to use your machine for hosting files, use it as a source to attack other systems, or just try some new exploits against it.

If you don't have any juicy information, you might not be a target for a skilled hacker, but you will always be a target for script kiddies. In hacker culture terms, *script kiddie* describes an inexperienced hacker who is using available tools, usually with a GUI, to do any malicious activity. Script kiddies lack technical expertise to write or

7. "Cenzic Desktop: Application Security for Cloud and Web," © 2012 Cenzic, Inc. All rights reserved. Cenzic, Inc., 655 Campbell Technology Parkway, Suite #100Campbell, CA 95008 [http://www.cenzic.com/products/desktop/index.html], 2013.

create any tools by themselves. They try to infect or deface as many systems as they can with the least possible effort. If they can't hack your system/site in a couple of minutes, usually they move to an easier target. It's rather different with skilled hackers, who seek financial or other benefits from hacking the system. They spend a lot of time just exploring the system and collecting as much information as possible before trying to hack it. The proper way of hacking is data mining and writing scripts that will automate the whole process, thus making it fast and hard to respond to.

10. DEFENSE IN DEPTH STRATEGY

Defense in depth is an information assurance (IA) strategy in which multiple layers of defense are placed throughout an IT system. Defense in depth addresses security vulnerabilities in personnel, technology, and operations for the duration of the system's life cycle. The idea behind this approach is to defend a system against any particular attack using several varying methods. It is a layering tactic, conceived by the National Security Agency (NSA) as a comprehensive approach to information and electronic security. Defense in depth was originally a military strategy that seeks to delay, rather than prevent, the advance of an attacker by yielding space in order to buy time. The placement of protection mechanisms, procedures, and policies is intended to increase the dependability of an IT system where multiple layers of defense prevent espionage and direct attacks against critical systems. In terms of computer network defense, defense-in-depth measures should not only prevent security breaches, they should give an organization time to detect and respond to an attack, thereby reducing and mitigating the impact of a breach. Using more than one of the following layers constitutes defense in depth:

- Physical security (deadbolt locks)
- Authentication and password security
- Antivirus software (host based and network based)
- Firewalls (hardware or software)
- Demilitarized zones (DMZs)
- Intrusion detection systems (IDSs)
- Intrusion prevention systems (IPSs)
- Packet filters (deep packet inspection appliances and stateful firewalls)
- Routers and switches
- Proxy servers
- Virtual private networks (VPNs)
- Logging and auditing
- Biometrics
- Timed access control
- Proprietary software/hardware not available to the public

11. VULNERABILITY ASSESSMENT TOOLS

There are many vulnerability assessment tools. Popular scanning tools according to www.sectools.org are listed here.

Nessus

Nessus is one of the most popular and capable vulnerability scanners, particularly for UNIX systems. It was initially free and open source, but they closed the source code in 2005 and removed the free "Registered Feed" version in 2008. It now costs $1,200 per year, which still beats many of its competitors. A free "Home Feed" is also available, though it is limited and only licensed for home network use. Nessus is constantly updated, with more than 46,000 plugins. Key features include remote and local (authenticated) security checks, a client/server architecture with a web-based interface, and an embedded scripting language for writing your own plugins or understanding the existing ones. The open-source version of Nessus was forked by a group of users who still develop it under the OpenVAS name.

GFI LANguard

This is a network security and vulnerability scanner designed to help with patch management, network and software audits, and vulnerability assessments. The price is based on the number of IP addresses you wish to scan. A free trial version of up to 5 IP addresses is available.

Retina

Commercial vulnerability assessment scanner by eEye. Like Nessus, Retina's function is to scan all the hosts on a network and report on any vulnerabilities found. It was written by eEye, well known for security research.

Core Impact

Core Impact isn't cheap (be prepared to spend at least $30,000), but it is widely considered to be the most powerful exploitation tool available. It sports a large, regularly updated database of professional exploits, and can do neat tricks like exploiting one machine and then establishing an encrypted tunnel through that machine to reach and exploit other boxes. Other good options include Metasploit and Canvas.

ISS Internet Scanner

Application-level vulnerability assessment Internet Scanner started off in 1992 as a tiny open-source scanner

by Christopher Klaus. Now he has grown ISS into a billion-dollar company with myriad security products.

X-Scan

A general scanner for scanning network vulnerabilities, X-Scan is a multithreaded, plug-in-supported vulnerability scanner. X-Scan includes many features, including full NASL support, detecting service types, remote OS type/version detection, weak user/password pairs, and more. You may be able to find newer versions available at the X-Scan site if you can deal with most of the page being written in Chinese.

12. SARA

Security Auditor's Research Assistant SARA is a vulnerability assessment tool that was derived from the infamous SATAN scanner. Updates are released twice a month and the company tries to leverage other software created by the open-source community (such as Nmap and Samba).

QualysGuard

A Web-based vulnerability scanner delivered as a service over the Web, QualysGuard eliminates the burden of deploying, maintaining, and updating vulnerability management software or implementing ad hoc security applications. Clients securely access QualysGuard through an easy-to-use Web interface. QualysGuard features 5000+ unique vulnerability checks, an inference-based scanning engine, and automated daily updates to the QualysGuard vulnerability knowledge base.

13. SAINT

Security Administrator's Integrated Network Tool (SAINT) is another commercial vulnerability assessment tool (like Nessus, ISS Internet Scanner, or Retina). It runs on Unix and used to be free and open source but is now a commercial product.

14. MBSA

Microsoft Baseline Security Analyzer (MBSA) is an easy-to-use tool designed for the IT professional that helps small and medium-sized businesses determine their security state in accordance with Microsoft security recommendations, and offers specific remediation guidance. Built on the Windows Update Agent and Microsoft Update infrastructure, MBSA ensures consistency with other Microsoft management products, including Microsoft Update (MU), Windows Server Update Services (WSUS), Systems Management Server (SMS), and Microsoft Operations Manager (MOM). Apparently MBSA, on average, scans over three million computers each week.[8]

15. SCANNER PERFORMANCE

A vulnerability scanner can use a lot of network bandwidth, so you want the scanning process to complete as quickly as possible. Of course, the more vulnerabilities in the database and the more comprehensive the scan, the longer it will take, so this can be a tradeoff. One way to increase performance is through the use of multiple scanners on the enterprise network, which can report back to one system that aggregates the results.

16. SCAN VERIFICATION

The best practice is to use few scanners during your vulnerability assessment, then use more than one scanning tool to find more vulnerabilities. Scan your networks with different scanners from different vendors and compare the results. Also consider penetration testing, that is, hire white/gray-hat hackers to hack your own systems.

17. SCANNING CORNERSTONES

All orphaned systems should be treated as hostile. Something in your organization that is not maintained or touched poses the largest threat. For example, say that you have a Web server and you inspect every byte of DHTML and make sure it has no flaws, but you totally forget to maintain the SMTP service with open relay that it is also running. Attackers might not be able to deface or harm your Web page, but they will be using the SMTP server to send out spam emails via your server. As a result, your company's IP ranges will be put into spammer lists such as spamhaus and spamcop.[9,10]

18. NETWORK SCANNING COUNTERMEASURES

A company wants to scan its own networks, but at the same time the company should take countermeasures to protect itself from being scanned by hackers. Here is a checklist of countermeasures (see checklist: "An Agenda For Action For The Use Of Network Scanning Countermeasures") to use when you're considering technical modifications to networks and filtering devices to

8. "SecTools.Org: Top 125 Network Security Tools," SecTools.Org [www.sectools.org], 2013.

10. Cisco Systems, Inc., ©1992–2010 Cisco Systems, Inc. All rights reserved. [www.spamcop.net], 2010.

An Agenda for Action for the Use of Network Scanning Countermeasures

Here is a checklist of network scanning countermeasures; and, if a commercial firewall is in use (check all tasks completed):

_____**1.** Filter inbound Internet Control Message Protocol (ICMP) message types at border routers and firewalls. This forces attackers to use full-blown TCP port scans against all your IP addresses to map your network correctly.

_____**2.** Filter all outbound ICMP type 3 unreachable messages at border routers and firewalls to prevent UDP port scanning and firewalking from being effective.

_____**3.** Consider configuring Internet firewalls so that they can identify port scans and throttle the connections accordingly. You can configure commercial firewall appliances (such as those from Check Point, NetScreen, and WatchGuard) to prevent fast port scans and SYN floods being launched against your networks. On the open-source side, many tools such as port sentry can identify port scans and drop all packets from the source IP address for a given period of time.

_____**4.** Assess the way that your network firewall and IDS devices handle fragmented IP packets by using fragtest and fragroute when performing scanning and probing exercises. Some devices crash or fail under conditions in which high volumes of fragmented packets are being processed.

_____**5.** Ensure that your routing and filtering mechanisms (both firewalls and routers) can't be bypassed using specific source ports or source-routing techniques.

_____**6.** If you house publicly accessible FTP services, ensure that your firewalls aren't vulnerable to stateful circumvention attacks relating to malformed PORT and PASV commands.

If a commercial firewall is in use, ensure the following:

_____**7.** The latest firmware and latest service pack is installed.

_____**8.** Antispoofing rules have been correctly defined so that the device doesn't accept packets with private spoofed source addresses on its external interfaces.

_____**9.** Investigate using inbound proxy servers in your environment if you require a high level of security. A proxy server will not forward fragmented or malformed packets, so it isn't possible to launch FIN scanning or other stealth methods.

_____**10.** Be aware of your own network configuration and its publicly accessible ports by launching TCP and UDP port scans along with ICMP probes against your own IP address space. It is surprising how many large companies still don't properly undertake even simple port-scanning exercises.[11]

reduce the effectiveness of network scanning and probing undertaken by attackers.

19. VULNERABILITY DISCLOSURE DATE

The time of disclosure of vulnerability is defined differently in the security community and industry. It is most commonly referred to as "a kind of public disclosure of security information by a certain party." Usually vulnerability information is discussed on a mailing list or published on a security Web site and results in a security advisory afterward. Mailing list named "Full Disclosure Mailing List" is a perfect example how vulnerabilities are disclosed to public. It is a must read for any person interested in IT security. This mailing list is free of charge and is available at http://seclists.org/fulldisclosure/.

The *time of disclosure* is the first date that security vulnerability is described on a channel where the disclosed information on the vulnerability has to fulfill the following requirements:

- The information is freely available to the public.
- The vulnerability information is published by a trusted and independent channel/source.
- The vulnerability has undergone analysis by experts such that risk rating information is included upon disclosure.

The method of disclosing vulnerabilities is a topic of debate in the computer security community. Some advocate immediate full disclosure of information about vulnerabilities once they are discovered. Others argue for limiting disclosure to the users placed at greatest risk and only releasing full details after a delay, if ever. Such delays may allow those notified to fix the problem by developing and applying patches, but they can also increase the risk to those not privy to full details. This debate has a long history in security; see full disclosure and security through obscurity. More recently a new form of commercial vulnerability disclosure has taken shape, as some commercial security companies offer money for exclusive disclosures of zero-day vulnerabilities. Those offers provide a legitimate market for the purchase and sale of vulnerability information from the security community.

11. Chris McNab, Network Security Assessment, O'Rielly, Chapter 4: IP Network Scanning [www.trustmatta.com/downloads/pdf/Matta_IP_Network_Scanning.pdf], pp. 36–72, 2013.

From the security perspective, a free and public disclosure is successful only if the affected parties get the relevant information prior to potential hackers; if they did not, the hackers could take immediate advantage of the revealed exploit. With security through obscurity, the same rule applies but this time rests on the hackers finding the vulnerability themselves, as opposed to being given the information from another source. The disadvantage here is that fewer people have full knowledge of the vulnerability and can aid in finding similar or related scenarios.

It should be unbiased to enable a fair dissemination of security-critical information. Most often a channel is considered trusted when it is a widely accepted source of security information in the industry (such as CERT, SecurityFocus, Secunia, www.exploit-db.com). Analysis and risk rating ensure the quality of the disclosed information. The analysis must include enough details to allow a concerned user of the software to assess his individual risk or take immediate action to protect his assets.

Find Security Holes before they Become Problems

Vulnerabilities can be classified into two major categories:

- Those related to errors made by programmers in writing the code for the software
- Those related to misconfigurations of the software's settings that leave systems less secure than they could be (improperly secured accounts, running of unneeded services, etc.)

Vulnerability scanners can identify both types. Vulnerability assessment tools have been around for many years. They've been used by network administrators and misused by hackers to discover exploitable vulnerabilities in systems and networks of all kinds. One of the early well-known Unix scanners, System Administrator Tool for Analyzing Networks (SATAN), later morphed into SAINT (Security Administrator's Integrated Network Tool). These names illustrate the disparate dual nature of the purposes to which such tools can be put.

In the hands of a would-be intruder, vulnerability scanners become a means of finding victims and determining those victims' weak points, like an undercover intelligence operative who infiltrates the opposition's supposedly secure location and gathers information that can be used to launch a full-scale attack. However, in the hands of those who are charged with protecting their networks, these scanners are a vital proactive defense mechanism that allows you to see your systems through the eyes of the enemy and take steps to lock the doors, board up the windows, and plug up seldom used passageways through which the "bad guys" could enter, before they get a chance.

In fact, the first scanners were designed as hacking tools, but this is a case in which the bad guys' weapons have been appropriated and used to defend against them. By "fighting fire with fire," administrators gain a much-needed advantage. For the first time, they are able to battle intruders proactively.[8] Once the vulnerabilities are found, we have to remove them (see sidebar, "Identifying and Removing Vulnerabilities").

Identifying and Removing Vulnerabilities

Many software tools can aid in the discovery (and sometimes removal) of vulnerabilities in a computer system. Though these tools can provide an auditor with a good overview of possible vulnerabilities present, they cannot replace human judgment. Relying solely on scanners will yield false positives and a limited-scope view of the problems present in the system.

Vulnerabilities have been found in every major operating system including Windows, Mac OS, various forms of Unix and Linux, OpenVMS, and others. The only way to reduce the chance of a vulnerability being used against a system is through constant vigilance, including careful system maintenance (e.g., applying software patches), best practices in deployment (e.g., the use of firewalls and access controls), and auditing during development and throughout the deployment life cycle.

20. PROACTIVE SECURITY VERSUS REACTIVE SECURITY

There are two basic methods of dealing with security breaches:

- The *reactive method* is passive; when a breach occurs, you respond to it, doing damage control at the same time you track down how the intruder or attacker got in and cut off that means of access so it won't happen again.
- The *proactive method* is active; instead of waiting for the hackers to show you where you're vulnerable, you put on your own hacker hat in relation to your own network and set out to find the vulnerabilities yourself, before anyone else discovers and exploits them.

The best security strategy employs both reactive and proactive mechanisms. Intrusion detection systems (IDS), for example, are reactive in that they detect suspicious network activity so that you can respond to it appropriately.

Vulnerability assessment scanning is a proactive tool that gives you the power to anticipate vulnerabilities and

keep out attackers instead of spending much more time and money responding to attack after attack. The goal of proactive security is to prevent attacks before they happen, thus decreasing the load on reactive mechanisms. Being proactive is more cost effective and usually easier; the difference can be illustrated by contrasting the time and cost required to clean up after vandals break into your home or office with the effort and money required to simply install better locks that will keep them out.

Despite the initial outlay for vulnerability assessment scanners and the time spent administering them, potential return on investment is very high in the form of time and money saved when attacks are prevented. *Threat Intelligence* is another example of proactive security methods. The goal of threat intelligence is to monitor dark corners of Internet for hacks, exploits, malicious code being sent to your networks. For example company XYZ, Inc. receives threat intelligence information that one of their web servers administrator level access is for sale in Russian underground forums. For this company it will be so much cheaper to shut down the server as soon as possible, so there will be the least amount of damage done.[12]

21. VULNERABILITY CAUSES

The following are examples of vulnerability causes:

- Password management flaws
- Fundamental operating system design flaws
- Software bugs
- Unchecked user input

Password Management Flaws

The computer user uses weak passwords that could be discovered by brute force. The computer user stores the password on the computer where a program can access it. User has so many accounts on different web sites, that it is impossible to have a different password and still remember it. The result: user uses the same password on many web sites (déjà vu anyone?).

Fundamental Operating System Design Flaws

The operating system designer chooses to enforce suboptimal policies on user/program management. For example, operating systems with policies such as *default permit* grant every program and every user full access to the entire computer. This operating system flaw allows viruses and malware to execute commands on behalf of the administrator.

Software Bugs

The programmer leaves an exploitable bug in a software program. The software bug may allow an attacker to misuse an application through (for example) bypassing access control checks or executing commands on the system hosting the application. Also the programmer's failure to check the size of data buffers, which can then be overflowed, can cause corruption of the stack or heap areas of memory (including causing the computer to execute code provided by the attacker).

Unchecked User Input

The program assumes that all user input is safe. Programs that do not check user input can allow unintended direct execution of commands or SQL statements (known as Buffer overflows, SQL injection, or other non-validated inputs). For example a form on the web page is asking how old are you? A regular user would enter 32, a hacker would try -3.2, which is somewhat legit input. The goal for entering bogus data is to find out how application reacts and monitor for input validation flaws. The biggest impact on the organization would be if vulnerabilities were found in core devices on the network (routers, firewalls, etc.), as shown in Figure 31.7.

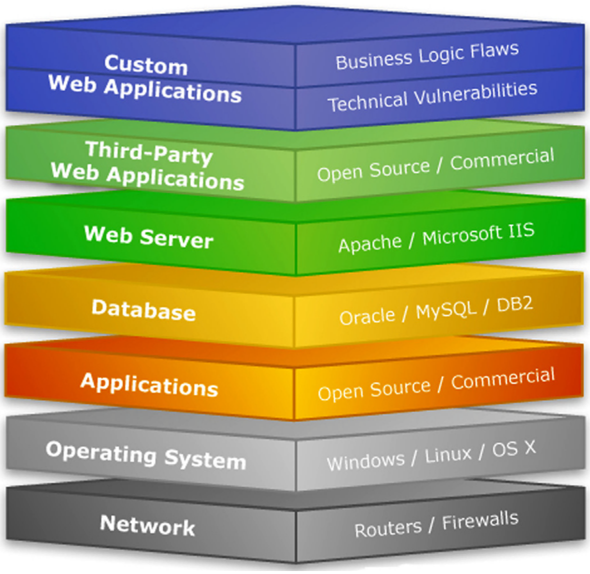

FIGURE 31.7 Vulnerabilities with the biggest impact.

12. "Threat Intelligence," © 2013 Demyo, Inc., Demyo, Inc. [http://demyo.com/services/threat-intelligence/], 2013.

22. DIY VULNERABILITY ASSESSMENT

If you perform credit-card transactions online, you're most likely PCI DSS compliant or working on getting there. In either case, it is much better to resolve compliancy issues on an ongoing basis rather than stare at a truck-load of problems as the auditor walks into your office. Though writing and reviewing policies and procedures is a big part of reaching your goal, being aware of the vulnerabilities in your environment and understanding how to remediate them are just as important. For most small businesses, vulnerability assessments sound like a lot of work and time that you just don't have. What if you could have a complete understanding of all vulnerabilities in your network and a fairly basic resolution for each, outlined in a single report within a couple of hours? Sound good? What if I also told you the tool that can make this happen is currently free and doesn't require an IT genius to run it? Sounding better?

It isn't very pretty and it's not always right, but it can give you some valuable insight into your environment. Tenable's Nessus vulnerability scanner is one of the most widely used tools in professional vulnerability assessments today. In its default configuration, all you need to do is provide the tool with a range of IP addresses and click Go. It will then compare its database of known vulnerabilities against the responses it receives from your network devices, gathering as much information as possible without killing your network or servers, usually. It does have some very dangerous plug-ins that are disabled by default, and you can throttle down the amount of bandwidth it uses to keep the network noise levels to a minimum. The best part about Nessus is that it's, very well documented, and used by over 75,000 organizations worldwide, so you know you're dealing with trustworthy product. I urge you to take a look Tenable's enterprise offerings as well. You might just be surprised at how easy it is to perform a basic do-it-yourself vulnerability assessment! Related links:

- Tenable's Nessus: www.nessus.org
- Tenable Network Security: www.tenablesecurity.com

23. SUMMARY

Network and host-based vulnerability assessment tools are extremely useful in determining what vulnerabilities might exist on a particular network. However, these tools are not useful if the vulnerability knowledge base is not kept current. Also, these tools can only take a snapshot of the systems at a particular point in time. Systems administrators will continually update code on the target systems and will continuously add/delete services and configure the system. All found vulnerabilities should be promptly patched (especially critical ones).

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Reporting capability is of growing importance to administrators in a documentation-oriented business climate where you must not only be able to do your job, you must also provide written proof of how you've done it.
2. True or False? Organizations have a tremendous opportunity to use information technologies to increase their productivity.
3. True or False? PCI DSS stands for Payment Card Information Data Security Standard.
4. True or False? There seems to be a certain amount of confusion within the security industry about the similarities between penetration testing and vulnerability assessment.
5. True or False? The theoretical goal of network scanning is elevated security on all systems or establishing a network-wide minimal operation standard.

Multiple Choice

1. What runs on all major computer operating systems, plus the Amiga.?
   A. Nmap
   B. Zenmap
   C. Security scanner GUI
   D. More popular Phase
   E. Attack Phase
2. What is an outstanding general-purpose scanner, but Web application-oriented scanners such as HP Web Inspect or Hailstorm will do a much better job of scanning a web application?
   A. Nessus
   B. SATAN
   C. Central
   D. Local
   E. User-level Rootkit scan
3. With localized scanning and central scanning verification, central scanning becomes a:
   A. Stateful firewall
   B. Virus
   C. Methodology
   D. Verification audit
   E. User-level Rootkit

4. What is an information assurance (IA) strategy in which multiple layers of defense are placed throughout an IT system?
   A. Physical security
   B. Authentication and password security
   C. Defense in depth
   D. Antivirus software
   E. Firewalls Rootkit
5. What is one of the most popular and capable vulnerability scanners, particularly for UNIX systems?
   A. Nessus
   B. GFI LANguard
   C. Retina
   D. Core Impact
   E. ISS Internet Scanner

EXERCISE

Problem

What will happen if a Vulnerability is exploited and who exploits vulnerabilities?

Hands-On Projects

Project

Will scanning interrupt or affect the servers?

Case Projects

Problem

What is Open Vulnerability and Assessment Language (OVAL®)?

Optional Team Case Project

Problem

How is OVAL different from commercial vulnerability scanners?

Chapter 32

Security Metrics: An Introduction and Literature Review

George O.M. Yee

Department of Systems and Computer Engineering, Carleton University, Ottawa, Canada K1S 5B6, gmyee@sce.carleton.ca

1. INTRODUCTION

We live in a world where attacks against computer systems are a fact of life. Barely a day goes by without headlines appearing about the latest systems compromised, in terms of Web sites being brought down by DDoS (distributed denial of service) attacks, or the loss of privacy due to malware-infected computers. In response, systems owners have invested more and more funds into various forms of protection mechanisms (firewalls, biometrics, data encryption) as well as improved design of systems and work flows to provide more resistance against these attacks. However, the return on these investments or the subsequent increase in the level of security has been largely unknown, leading to the following dilemmas:

- How much more do I need to spend to be "safe" from attack?
- Will the changes made to my software to improve security be effective?
- Are my company's work flows or processes sufficiently secure?
- How will adding the third-party software component impact security?
- How can legislation requiring certain levels of security be enforced if the level of security is unknown?

These questions can be answered if there is some way to measure the cyber system's level of security. Properly defined, effective *security metrics* appear to be the solution. An analogy can be made with performance engineering, where there is a need to know if the performance of a computer system is sufficient to satisfy users when they are under a certain processing load. A performance analysis to obtain *performance metrics* such as throughput and service time is an effective approach to knowing if the performance is sufficient, and if not, identifying the location of performance bottlenecks. Similarly, in the security domain, it should be possible to perform a security analysis of a computer system to obtain security metrics that would indicate whether the system is secure from various forms of attack, and if not, where and what are the vulnerabilities.

Security metrics do exist and are being used. However, most of them are far from giving the results described above. They can be ineffective and not meaningful. For example, a traditional metric is the number of viruses detected and eliminated, say at a firewall. This metric is not meaningful since (a) it says nothing about the number of viruses that were not detected and that got through, and (b) it does not explain why so many viruses are trying to get through in the first place [1]. Rather, a security metric should:

- Measure quantities that are meaningful for establishing the security posture of a computer system or of an organization.
- Be reproducible.
- Be objective and unbiased.
- Be able to measure a progression toward a goal over time.

More details on what makes a good (or a bad) security metric are given in Section 3. The above qualities of a good security metric also describe certain metrics that have a basis in science, such as the throughput metric in performance engineering. Throughput measures the number of jobs completed per second by a computing system. It is a quantitative measure of a computing system based on the laws of physics. It is also meaningful, reproducible, objective, and unbiased, and it can measure the improving performance of a system over time toward a throughput goal. This leads to the question of what sort of scientific framework could give rise to such science-based metrics. This topic will be discussed further in Section 3.

An interesting practical application of security metrics is in determining the security posture of a computer

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00032-5

system in real time. One envisages a security dashboard that displays security metrics associated with vulnerability points. The dashboard would display security alerts corresponding to strategic subsets and groupings of the metrics that exceed critical thresholds. Security officers monitoring the dashboard would then be able to take remedial action, upon which the security alerts would be replaced by "system back to normal" messages. One can further envisage the dashboard as having intelligence sufficient to recommend courses of remedial action appropriate to particular security alerts. The possibility of achieving this vision based on commercial systems now available will be assessed in Section 5. The objectives of this chapter are:

1. To introduce the reader with little or no background in security metrics to the topic
2. To discuss the nature of security metrics
3. To explain how one can get started in using security metrics
4. To show the reader where to find further information by presenting the results of a literature search (including research papers) on security metrics.

The rest of this chapter is organized as follows. Section 2 further elaborates on the need for security metrics. Section 3 discusses the nature of security metrics, including the need to put security metrics on a scientific basis and what that means; Section 4 gives an overview on how one could get started using security metrics; Section 5 provides an assessment of the feasibility of achieving a security dashboard that is driven by security metrics; Section 6 presents the results of a literature search on security metrics; and Section 7 gives conclusions.

2. WHY SECURITY METRICS?

Over 100 years ago, Lord Kelvin, the distinguished British mathematical physicist and engineer, observed that measurement is vital to knowledge and to continued progress in physical science. Lord Kelvin stated that "to measure is to know," and "if you can not measure it, you can not improve it."

These observations are evident in many activities in our modern world. One has only to recall school exams, and at the time of this writing, the 2012 London Olympics. Indeed, the Olympics is fraught with measurement, and an athlete depends on measuring his or her progress in order to improve in his or her chosen sport. Returning to the topic of computer systems performance that was mentioned in the Introduction, we note that measuring the performance of a computer system prior to its deployment in a highly demanding environment is the only way to know in advance if it will perform adequately once deployed. In addition, in order to improve the performance, one has to know where the performance bottlenecks lie, something that can only be found by measuring it. Thus, it appears that Lord Kelvin's words are applicable to many modern activities, as they were during his own time.

These observations on measurements are also relevant to the information technology (IT) world. Organizations and consumers rely on information technology to deliver goods and services. Information technology heads are challenged to use computer systems effectively and to protect them from security threats and risks. Many efforts have been made to develop security measurements to help organizations make informed decisions about the design of systems, the selection of controls, and the efficiency of security operations. But the development of standardized metrics for computer system security has been a difficult challenge, and past efforts have only met with partial success (see Section 3). Security metrics are needed to:

- Provide a quantitative and objective basis for security operations.
- Support decision making (is investment in more security controls needed)?
- Support software quality since software security is part of software quality,
- Support the reliable maintenance of security operations (how often do users need to change their passwords)?
- Support the incremental improvement of software's resistance to attacks.

This list is by no means exhaustive, but it does serve to illustrate the usefulness of good security metrics. In addition, the following are the main uses of security metrics [2]:

- "Strategic support—Assessments of security properties can be used to aid different kinds of decision making, such as program planning, resource allocation, and product and service selection.
- Quality assurance—Security metrics can be used during the software development life cycle to eliminate vulnerabilities, particularly during code production, by performing functions such as measuring adherence to secure coding standards, identifying likely vulnerabilities that may exist, and tracking and analyzing security flaws that are eventually discovered.
- Tactical oversight—Monitoring and reporting of the security status or posture of an IT system can be carried out to determine compliance with security requirements (policy, procedures, and regulations), gauge the effectiveness of security controls and manage risk, provide a basis for trend analysis, and identify specific areas for improvement."

It should be clear from the above that security metrics play very important roles in today's computing systems.

3. THE NATURE OF SECURITY METRICS

Security metrics as quantifiers of the effectiveness of the organization's security practices over time have always been difficult to define and evaluate. How can an organization determine whether it is secure? This can only be truly determined by the organization undergoing a real crisis. Yet, such a crisis is exactly what the security controls were designed to prevent.

Traditional Security Metrics

Traditional security metrics have not been developed in a rigorous, systematic manner [1]. It may in fact, have given rise to false impressions of security, leading to unsafe or ineffective implementations of security controls.

The Organization Perspective

A security metric is therefore given the task of measuring the security of the organization, which is discernible only when the organization is in a security crisis, thereby defeating the whole point of having the metric in the first place. An important requirement of a security metric then is that it is capable of measuring the organization's security level at any time and not only when the organization is in a crisis. The bottom line is that management needs some way to measure the organization's security level. Organizations need to ask:

- How many *security controls* does it take to be "safe"?
- *When* does the organization know it is "safe"?
- How can the cost of new security controls be *justified*?
- Is the organization getting *good value* for its money?
- How can the organization *compare* its security posture with that of other similar organizations and with best practices?

Traditionally, these questions are answered using risk assessment. In particular, the answers relate to how much residual risk the organization is willing to accept, depending on business needs and budget limits. However, risk management may be a red herring and may not necessarily lead to stronger security.

Consider, for example, a risk assessment that lists a number of threats, along with the cost to mitigate each threat or risk. Some items on the list would be very low cost, while other items would be very expensive (see Figure 32.1). Often, management may choose to purchase the most security controls for the least amount of money, possibly ignoring the most expensive controls. Management assumes that buying more inexpensive controls is better value than buying fewer expensive ones. Thus, there is a tendency to buy large numbers of less expensive security tools and avoid the more expensive, less glamorous controls. The latter tends to be organizational, requiring cultural change (disaster recovery plan) rather than specific self-contained solutions (such as firewalls and intrusion detection systems—IDSs). In carrying out such a purchase policy, management believes it is buying more security for less money.

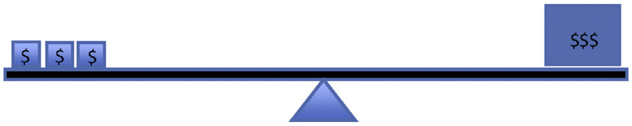

FIGURE 32.1 Is buying more inexpensive security controls better than buying fewer but more expensive ones?.

However, how can it be said that more security is purchased? What increased security does each additional purchase achieve, and how can the organization determine this? How do we even know that the purchases have been made in the correct order? Perhaps the organization is being exposed to *more* risk because of the haphazard way in which the security controls were obtained?

Security metrics programs need to be built from the ground up to allow for new approaches to these traditional security metrics problems. A more systematic and even scientifically based approach (see below) to security metrics can:

- Come up with reproducible and justifiable measurements
- Objectively measure something of value to the organization
- Determine real progress in security posture
- Apply to a broad range of organizations while producing consistent results
- Fix the order in which security controls should be applied
- Help determine the resources needed to apply to a security program

Issues Associated with Definition and Application

To be called a metric, a measurement has to be combined with time. Furthermore, a metric by itself is not going to save an organization that is in trouble with its security posture. It is necessary to think through and analyze the true meaning of the metric. The art is to develop security metrics that are simple and that provide useful management information corresponding to security-related

objectives. The metrics have to inform the organization by demonstrating progress.

Clearly, a security metric needs to count or measure *something*. But count or measure what? How can security be measured? Consider the following security metrics (in italics) [1] that are common but problematic in that they ignore the attendant core issues:

- *Number of computer viruses or malware detected*. The intended use of this metric is to measure the effectiveness of the anti-malware controls. However, it fails to consider why so much malware is getting through in the first place, and what about the malware that got through but were undetected!
- *Number of security incidents and investigations*. This metric presumably measures the effectiveness of security events monitoring. However, it does not consider the thresholds at which the incident or investigation is triggered. Nor does it consider their causes; for example, are incidents triggered due to flaws in work processes?
- *Cost of security breaches*. This metric is intended to measure the true business loss due to security failures. However, it ignores the residual risks that the organization chose to live with. Furthermore, it does not differentiate between costs incurred for normal operations, despite safeguards that were in place, or costs that result from abnormal conditions such as crises or disasters.
- *Resources assigned to security functions*. The intended use of this metric is to measure the true business cost of running a security program. However, it fails to consider the causes of high cost such as the possibility that people may be less productive due to inefficient tools or procedures.
- *Compliance with security policy*. This metric is intended to measure the level of compliance or adhesion to security goals. However, it can be misleading since it fails to consider how compliance is related to effectiveness, the order of compliance that may be relevant, and what happens once compliance is achieved—will the security program be complete then?

A security metric for an organization should measure the quality of the organization's security program and be capable of showing progress. The latter is important so that one can know if new investments in improving security are making any difference. None of the above metrics really possess these capabilities. The following illustration shows why incident totals are unreliable:

Imagine a small town with one police officer. He does no other police work other than patrolling the highway with a radar gun, pulling over hundreds of speeders. Now imagine a large town with many police officers. They do not use radar guns and have caught very few speeders but have a large defensive driving program and an active anti-drunk-driving program. Is the small town safer than the large town? The count of speeders is only as good as the sensing mechanism, but that number has no depth to it. What about the small town with nonspeeders who are drunk—are they not potentially more dangerous? [1]

Consider the anti-malware tool in light of this illustration. The fact that the tool detected a large amount of malware probably makes the security team feel good that the tool works and that so much malware has been caught. However, this says very little about the organization's security level. Why is so much malware present in the first place? How much malware remains undetected? What does it say about the quality of the security program? In fact, just the opposite may be what we want: The tool doesn't detect any malware because malware is unable to penetrate the security controls that are in place!

Time spent on a security-related task (software patching, security incident investigation) is often used as a security metric. This may be useful from a project management point of view in order to ensure that there is sufficient time to complete a project, but it is next to useless as a measure of security. This is because more time spent does not necessarily translate into better security. For example, the additional time may have been due to inefficient procedures or work processes. Moreover, such procedures may have been responsible for triggering the incidents that called for the investigation (security-related task) in the first place!

The business cost of a security incident is another unreliable security metric. This metric comes with the built-in assumption that something bad has happened, but what if that something has already been considered as acceptable to the organization in terms of the residual risk it is willing to live with? On the other hand, the security incident may in fact have been caused by poor security practices. Or perhaps one of these two possibilities happened, but the incident management was so good that the costs were kept to a minimum. How can these three possibilities be separated? This metric may measure the effectiveness of incident response in terms of minimizing the business cost, but it may not be a good rating of the quality of the organization's security practices since it cannot distinguish whether or not the costs were due to poor security practices.

Security metrics should have the following **ideal characteristics**. They should

- *Measure quantities that are meaningful for establishing the security posture of a computer system or of an organization*. As discussed above, some traditional security metrics fail to measure the security level, which should be their first objective.

- *Have results that are reproducible*. This means that the value of the security metric should be the same as the original value if reevaluated by another party, given that the factors on which the metric is evaluated remain the same. It will be seen below that this is a key requirement of being "scientifically-based."
- *Be objective and unbiased*. This requirement is self explanatory.
- *Be able to measure a progression toward a goal over time*. As already mentioned, it is important to be able to measure over time whether or not investments in improving security have in fact improved security [1].

Unfortunately, traditional security metrics found in practice lack one or more of the above characteristics. Such metrics were haphazard and opportunistic in the sense that whatever measures were readily available were taken up and reported. Moving even beyond the ideal characteristics of a security metric above, security metrics should be "scientifically based." The meaning of this will be discussed in the next section.

Scientifically Based Security Metrics

It would be very useful to have computer security based on science, similar to computer systems performance being based on the science of physics. For then security could be analyzed, just as performance is analyzed, and security metrics could be systematically derived and predicted, just as performance metrics are derived and predicted. Unfortunately, it is not known at the time of this writing that security can be based on science, due to at least two fundamental problems [3] as follows:

> Problem 1: "The first is the difference between mathematical abstractions [for security metrics] and real implementations. The gap between theoretical cryptography results and practical cryptanalysis illustrates this: although no one has found a fast factoring algorithm, RSA implementations are regularly broken because of side channels (such as timing and power consumption), poor random-number generation, insecure key storage, message formats and padding, and programming bugs.[1] For system security, the gap between models simple enough to use for metrics and actual implementations is even larger. To make progress, we need metrics that work on more concrete models of actual systems, or ways to build systems that refine models without introducing security vulnerabilities." In other words, security metrics must be simple enough to understand, but by so being, they cannot capture enough of what is going on in a computer system to accurately reflect security levels.
>
> Problem 2: "The second problem is that it seems unlikely that we can reason well about adversary creativity. This argues for metrics that assume that adversaries can efficiently search the entire space of possible actions. Perhaps we can develop complexity metrics that analyze that space and the maximum effectiveness of different search strategies." In other words, to understand the security of a computer system, it is necessary to understand attacker creativity in creating new attacks. However, at the present time, we are not very good at capturing and predicting this behavior. This then calls for metrics that assume that the attacker is capable of launching every possible attack, which are difficult to design since we would need to know every possible attack.

However, the preceding assumes basing security on a "weak sense of science" [3] and the "strong sense of science" (explained below). It is possible to base security on the "methodological sense of science." Let us examine these senses of science more closely. Three interpretations of science can be considered for security metrics [3], as follows:

- *Weak sense*: science as the generalization and systematization of knowledge—for example, consider the body of knowledge within physics, where laws and descriptions of behavior have been systematized and interwoven into an integral whole.
- *Strong sense*: science used to develop laws with which predictions can be made—for example, in physics, laws of motion have been developed and used to predict the future position of planets.
- *Methodological sense*: science used for research by forming hypotheses and proving or disproving the hypotheses with experiments. The results of the experiments must be confirmable by independent experimenters. Hence the experiments must be repeatable and yield the same results. This is the embodiment of the scientific method, and established sciences have in fact been built up in this fashion.

Basing security metrics on the weak sense of science is currently at best unknown as there has not been sufficient research to show that it is even possible outside of perhaps a highly specialized subarea of security. Basing the metrics on the strong sense is likewise untenable since it is more likely that laws can be developed only after systematization of the knowledge (the strong sense is more likely after the weak sense has been established). This leaves the methodological sense, which appears to be a possible basis on which a framework for computer security metrics can

1. J.P. Degabriele, K.G. Paterson, G.J. Watson, Provable security in the real world, *IEEE Security & Privacy* 9 (3) (2011) 33–41.

be developed. Such a development, however, is currently undergoing research and is beyond the scope of this chapter. However, the reader is invited to consult this author's papers on this subject in the near future.

Assuming that scientifically based security metrics are available, the following question now arises: What type of security metrics should be used—those based on science or those having the ideal characteristics? It is recommended that both types can be used. The choice can be made based on practicality and system requirements. Scientifically based metrics would be more rigorous and therefore require more work to define and evaluate. Perhaps scientifically based metrics can be reserved for critical systems such as those involving public utilities, public safety, hospital systems, and defense applications, which have more stringent requirements for security.

4. GETTING STARTED WITH SECURITY METRICS

As a security professional in your organization, you would like to start a security metrics program and begin using security metrics. But how do you start such a program (see checklist: An Agenda for Action for Getting Started with Security Metrics")?

An Agenda for Action for Getting Started with Security Metrics

This checklist consists of some essential items that must first be in place, after which suggestions are given (in no particular order) to guide you in starting a security metrics program in your organization [4] (check all tasks completed): Essentials: The following items are essential for any successful security metrics program:

_____1. **Design your security metrics based on ideal characteristics**.

_____2. **Make sure you collect and store all the data needed for the metrics as specified in your design of the metrics**. This task may sometimes be automated by programming the system to automatically output the data needed to a repository.

_____3. **Obtain a picture of how metrics-minded your organization is through discussion with management and co-workers**. Ensure that everyone understands and buys in to processes that include metrics, which will be critical when you collect the data needed for the metrics.

Suggestions for Security Metrics Design: The following Suggestions are Essential for any Successful Security Metrics Design:

_____4. **Base your security metrics on the ideal characteristics.** Strive to base your security metrics on the ideal characteristics as described in Section 3.

_____5. **Use your service-level agreement to guide your metrics design.** Your organization's security policies or service-level agreements will point to areas for which security metrics may be needed. Use them to refine your measurement targets. By so doing, you will be relating what you measure to what is expected of you, and your organization (especially upper management) will more immediately recognize the value of your results.

_____6. **Start with basic measurements, understand them, then expand.** Start with a basic metric that is easy to understand and then work to make that metric more useful or replace it with a better one that you've discovered along the way. Be well organized and prioritize your efforts so that you can build up and maintain a portfolio of metrics that have maximal value.

Suggestions for Organization and Management:

_____7. **Form a team of stakeholders as early as possible.** As soon as possible, contact and put together a cross-functional team of metrics-minded people to build the plan around collecting, analyzing, reporting, interpreting, and responding to security metrics. Work with the experts who understand the data, and the management who will need to champion changes throughout the organization.

_____8. **Define your metrics data repository.** A central agreed location for storing trusted data required for metrics evaluation will help to create confidence and trust in the data. Also, it may save you much time defending the data later on, should questions arise over its reliability.

_____9. **Be consistent in using your metrics.** Don't spend a month on observing and analyzing and then move on if nothing is found. Consistent, steady vigilance is the key to identifying trends or variances; erratic monitoring and analysis will mislead you into a false sense of security and reduce your ability to continuously reflect and refine based on known patterns.

_____10. **Be ready to change based on your findings.** A common behavioral pattern is to take a finding, create a countermeasure around it, and then never look back. Be intellectually and ethically honest when you make new discoveries, particularly if they show a need to change an established rule, position, or policy. Learn to be comfortable with the idea that you may learn something new that will require a policy or process change.

_____11. **Be open to incorporating expertise and data from others.** Since attacks are often not limited to one area, you may need to integrate data from other system components into your analysis. In this

case, ask for input from teams who know these other components better. They may shed light on interdependencies or relationships that are critical to better metric design. Leverage the findings established together with these teams to extract any support that may be needed from managers.

_____**12. Test your analytics.** Carry out a Metrics Penetration Test (MPT), which is a test to determine if your analytic procedures will zero in on the behaviors you are trying to isolate. For example, have a colleague attempt to crack a login password at an odd hour of the day to see if your "Unusual Login Attempts" metric triggers the flags you expect to see. Incorporate the results from these MPTs in operational reviews to continue evolving and maturing your analytic methodologies.

Additional advice for establishing a security metrics program can be found in books such as Jaquith [5] and Hayden [6]. In addition, NIST [7] provides guidelines for establishing measures for assessing security controls and other security-related activities.

5. METRICS IN ACTION—TOWARDS AN INTELLIGENT SECURITY DASHBOARD

SIEM (Security Information and Event Management) describes security dashboard-like commercial applications or services that are widely available from security vendors. According to Wikipedia[2], SIEM technology "provides real-time analysis of security alerts generated by network hardware and applications. SIEM solutions come as software, appliances or managed services, and are also used to log security data and generate reports for compliance purposes". The same Wikipedia page also gives the following list f SIEM capabilities:

- **Data Aggregation:** SIEM/LM (log management) solutions aggregate data from many sources, including network, security, servers, databases, applications, providing the ability to consolidate monitored data to help avoid missing crucial events.
- **Correlation:** looks for common attributes, and links events together into meaningful bundles. This technology provides the ability to perform a variety of correlation techniques to integrate different sources, in order to turn data into useful information.
- **Alerting:** the automated analysis of correlated events and production of alerts, to notify recipients of immediate issues.
- **Dashboards:** SIEM/LM tools take event data and turn it into informational charts to assist in seeing patterns, or identifying activity that is not forming a standard pattern.
- **Compliance:** SIEM applications can be employed to automate the gathering of compliance data, producing reports that adapt to existing security, governance and auditing processes.
- **Retention:** SIEM/SIM [Security Information Management] solutions employ long-term storage of historical data to facilitate correlation of data over time, and to provide the retention necessary for compliance requirements.

The question at hand is: Is it possible to use SIEM technology as a base up on which to build an intelligent security dashboard that displays security alerts and responds to the alerts by either suggesting corrective action or automatically taking corrective action (depending on the action), or both? The above list of SIEM capabilities suggests that the "alerting" and "dashboard" capabilities map directly to the security dashboard's display of security alerts, and that the "data aggregation" and "correlation" capabilities map directly to the security dashboard's suggesting or taking of corrective action. Thus it does seem viable to use SIEM technology as the base on which to build the security dashboard. Additional research is required to determine what security metrics should be used to trigger the security alerts. In addition, research is needed to know how to construct the security dashboard's corrective action engine, which may be built using artificial intelligence techniques. The construction of an intelligent security dashboard based on SIEM technology does indeed appear feasible.

6. SECURITY METRICS IN THE LITERATURE

This section presents the results of a literature search using the following sources: the Internet, the IEEE Xplore and ACM Digital Library databases, and the homepages of university researchers. The publications found can be categorized as concerning:

- The nature of security metrics
- Measuring the security of a computer system
- Managing IT security risks
- Measuring the effectiveness of a security process

Measuring the security of a computer system differs from the other categories in that (i) it considers the component makeup of the computer system, (ii) it is about the use of scientific tools (modeling) to measure the security, and (iii) it only measures the security of the computer

2. "Security information and event management", accessed Mar. 27, 2012 at: http://en.wikipedia.org/wiki/Security_information_and_event_management.

system and not other aspects such as operational security or security process. Note that a publication may appear in more than one category.

It should also be noted that a publication may not fit neatly within a particular category. This is natural since security metrics may have a different meaning for different people, and different authors approach the subject from their own varied backgrounds and environments. The above categories do, however, help to group the papers in a broad sense. Of course, the security metrics coverage within these publications is limited by the data sources searched, since not all research is published or published in these sources. Nevertheless, one can say that given the dominance of IEEE and ACM publication repositories over other sources, this coverage is reasonably high.

The following sections divide up the publications into tables according to each of the categories mentioned above. References to the publications in each table are of the form "Table *n* [*i*, *j*, *k*, . . .]", for publications *i*, *j*, *k*, . . . in Table *n*.

The Nature of Security Metrics

Table 32.1 lists the publications in this category, which treats questions such as "how is a security metric defined?" (Table 32.1 [3,4,7]), "what makes a good security metric?" (Table 32.1 [4,6,7]), "what is a security metrics taxonomy?" (Table 32.1 [3]), "are security metrics scientifically based?" (Table 32.1 [2,5]), "what are good areas for security metrics research?" (Table 32.1 [5]), and "who are the U.S. industrial and government players in security metrics, and what security metrics initiatives have they undertaken?" (Table 32.1 [1]). Publications Table 32.1 [2,4–6] elaborate the ideas of Section 3 by discussing what makes a good security metric and a scientific basis for security metrics.

Measuring the Security of a Computer System

Table 32.2 lists the publications in this category, which contains the largest number of publications of all the categories. These papers propose a range of techniques that use metrics to evaluate the security of a computer system and mostly apply to the software. The techniques involve the computer system's components and generally do not treat supporting areas such as software development practice, security operations, or security process. The papers here are based on various frameworks and serve to illustrate the earlier discussion of a scientific framework for computer system security metrics.

TABLE 32.1 The Nature of Security Metrics.

No.	Publication	Summary
1	"Measuring Cyber Security and Information Assurance," IATAC SOAR, May 8, 2009.	Provides broad coverage of United States, including laws, standards, best practices, government programs, industry initiatives, measurable data, tools, and technologies.
2	S. Stolfo, S. Bellovin, D. Evans, "Measuring Security," *IEEE Security & Privacy*, May/June 2011.	Discusses a scientific basis for security and security metrics with examples and ideas for research; focuses on security of a computer system.
3	R. Savoia, "Towards a Taxonomy for Information Security Metrics" QoP'07, 2007.	Proposes a high-level security metrics taxonomy for Information Communications Technology (ICT) product companies; gives an example of a security metrics taxonomy.
4	D. Chapin, S. Akridge, "How Can Security Be Measured?" *Information Systems Control Journal*, Vol. 2, 2005.	Discusses what is wrong with traditional security metrics, giving characteristics of good metrics; discusses security maturity models with examples.
5	Wayne Jansen, "Directions in Security Metrics Research," NIST, April 2009.	Overviews security measurement and proposes possible research areas such as formal models of security measurement and artificial intelligence techniques.
6	O. Saydjari, "Is Risk a Good Security Metric?" Panel, Proceedings of QoP'06, 2006.	Succinct descriptions of risk as a security metric, alternative security metrics, and what makes a good metric.
7	Andrew Jaquith, *Security Metrics: Replacing Fear, Uncertainty, and Doubt*, Addison-Wesley, 2007.	Discusses security metrics for enterprise application; security metrics applied broadly, not only to computing systems but also to all sorts of enterprise processes.
8	Lance Hayden, IT Security Metrics: *A Practical Framework for Measuring Security & Protecting Data*, McGraw-Hill Osborne Media, June 2010.	Similar to the Jaquith book in its focus on the enterprise; covers security metrics in terms of effectiveness, implementation, operations, compliance, costs, people, organizations; includes four case studies.

TABLE 32.2 Measuring the Security of a Computer System.

No.	Publication	Summary
1	S. Stolfo, S. Bellovin, D. Evans, "Measuring Security," *IEEE Security & Privacy*, May/June 2011.	Discusses scientific basis for security and security metrics with examples and ideas for research; focuses on security of a computer system.
2	Wayne Jansen, "Directions in Security Metrics Research," NIST, April 2009.	Overviews security measurement and proposes possible research areas such as formal models of security measurement and artificial intelligence techniques.
3	M. Howard, J. Pincus, J. Wing, "Measuring Relative Attack Surfaces," in *Computer Security in the 21st Century*, Springer, pp. 109–137, 2005.	Proposes "attack surfaces" as a measure of one system's security relative to another; an attack surface is described along three dimensions: targets and enablers, channels and protocols, and access rights.
4	M. Howard, "Attack Surface: Mitigate Security Risks by Minimizing the Code You Expose to Untrusted Users," 2004.	Offers ractical advice to developers on how to reduce the attack surface of their code; based on actual Microsoft products such as Windows XP and Windows Server 2003.
5	L. Wang, A. Singhal, S. Jajodia, "Toward Measuring Network Security Using Attack Graphs," Proceedings of QoP'07, 2007.	Proposes a framework for assessing the security of a network based on attack graphs or access paths for attack; for example, given two networks, if one has more paths of attack than the other, it is the less secure of the two; references Table 32.2 for attack resistance.
6	S. Noel, L. Wang, A. Singhal, S. Jajodia, "Measuring Security Risks of Networks Using Attack Graphs," *International Journal of Next-Generation Computing*, Vol. 1, No. 1, pp 113–123, 2010.	Gives an expanded version of Table 32.2[5]; provides a method for quantitatively analyzing the security of a network using attack graphs; the attack graphs are first populated with known vulnerabilities and likelihoods of exploitation and then "exercised" to obtain a metric of the overall security and risks of the network.
7	L. Wang, S. Jajodia, A. Singhal, S. Noel, "k-Zero Day Safety: Measuring the Security Risk of Networks against Unknown Attacks," Proceedings of 15th European Symposium on Research in Computer Security (ESORICS 2010), Springer-Verlag Lecture Notes in Computer Science (LNCS), Vol. 6345, 20–22 September, pages 573–587, 2010.	Proposes "k-zero day safety" as a security metric that counts the number of unknown zero day vulnerabilities that would be required to compromise a network asset, regardless of what those vulnerabilities might be. The metric is defined in terms of an abstract model of networks and attacks. Algorithms for computing the metric are included.
8	L. Wang, A. Singhal, S. Jajodia, "Measuring the Overall Security of Network Configurations Using Attack Graphs," Proc. 21st Annual IFIP WG 11.3 Working Conference on Data and Applications Security (DBSec 2007), Springer Lecture Notes in Computer Science, Vol. 4602, Steve Barker and Gail-Joon Ahn, eds., Redondo Beach, CA, pages 98–112, 2007.	Proposes an attack graph-based attack resistance metric for measuring the relative security of network configurations; incorporates two composition operators for computing the cumulative attack resistance from given individual resistances and accounts for the dependency between individual attack resistances; referenced by Table 32.2[5] for attack resistance.
9	L. Wang, T. Islam, T. Long, A. Singhal, S. Jajodia, "An Attack Graph-Based Probabilistic Security Metric," Proceedings of 22nd Annual IFIP WG 11.3 Working Conference on Data and Applications Security (DBSEC 2008) , Springer-Verlag Lecture Notes in Computer Science (LNCS), Vol. 5094, pages 283–296, 2008.	Proposes an attack graph-based metric for the security of a network that incorporates the likelihood of potential multistep attacks combining multiple vulnerabilities in order to reach the attack goal; the definition of the metric is claimed to have an intuitive and meaningful interpretation that is useful in real-world decision making.
10	A. Singhal, X. Ou, "Techniques for Enterprise Network Security Metrics," Fifth Cyber Security and Information Intelligence Research Workshop (CSIIRW '09), Knoxville, TN, USA, 2009.	Presents an attack graph-based method for evaluating the security of a network based on likelihood of attack (similar to Table 32.2); stresses the derivation of the metric based on composition of component vulnerabilities whose security levels are already known. This is a short paper with accompanying slides.
11	M. Frigault, L. Wang, A. Singhal, S. Jajodia, "Measuring Network Security Using Dynamic Bayesian Network," Proceedings of QoP'08, 2008.	A Dynamic Bayesian Network (DBN) model is used to capture the dynamic nature of vulnerabilities that change over time. An attack graph is converted to a DBN by applying conditional probabilities to the nodes, calculated from the Common Vulnerabilities Scoring System (CVSS). The security of the network is calculated from the probabilities of the attacks being successful.

TABLE 32.2 (Continued)

No.	Publication	Summary
12	M. Frigault, L. Wang, "Measuring Network Security Using Bayesian Network-Based Attack Graphs," Annual IEEE International Computer Software and Applications Conference, 2008.	Proposes measuring network security using Bayesian network-based attack graphs so that relationships such as exploiting one vulnerability makes another vulnerability easier to exploit may be captured; differs from Table 32.2 in that Table 32.2 uses Dynamic Bayesian Networks, whereas this paper uses regular Bayesian networks.
13	L. Krautsevich, F. Martinelli, A. Yautsiukhin, "Formal Approach to Security Metrics. What Does 'More Secure' Mean for You?" Proceedings of ECSA 2010, 2010.	Initial proposal and analysis of a number of mathematically based definitions of security metrics such as "number of attacks", "minimal cost of attack", "maximal probability of attack", and even "attack surface" from Table 32.2[3].
14	C. Wang, W. Wulf, "Towards a Framework for Security Measurement," Proceedings of 20th National Information Systems Security Conference, 1997.	Proposes an initial framework for estimating the security strength of a system by decomposing the system into its security sensitive components and assigning security scores to each component; aggregate the component scores to get an estimate for the security strength of the system.
15	P. Halonen, K. Hätönen, "Towards Holistic Security Management through Coherent Measuring," Proceedings of ECSA 2010, 2010.	Discusses the problems of applying security metrics to telecommunication systems; compares security metric taxonomies, and discusses the need for security impact metrics; presents a broad view of security metrics.
16	D. Mellado, E. Fernández-Medina, M. Piattini, "A Comparison of Software Design Security Metrics," Proceedings of ECSA 2010, 2010.	Surveys various security metrics and standards that may be applicable to software design; compares the relevance of the various approaches to security properties such as authenticity and confidentiality.
17	J. Wang, H. Wang, M. Guo, M. Xia, "Security Metrics for Software Systems," Proceedings of ACMSE '09, 2009.	Presents a security metrics formulation in terms of weaknesses and vulnerabilities, rated by CVSS scores for CVE (Common Vulnerabilities and Exposures) names; does not show how one would determine such scores for a brand-new piece of software; not clear how the final security metric can be used to improve security.
18	R. Scandariato, B. De Win, W. Joosen, "Towards a Measuring Framework for Security Properties of Software," Proceedings of QoP '06, 2006.	Claims that software has security properties that can be measured, much like it has maintainability properties such as complexity; proposes a number of software security properties along with corresponding metrics.
19	O. Saydjari, "Is Risk a Good Security Metric?" Panel, Proceedings of QoP'06, 2006.	Presents succinct descriptions of risk as a security metric, alternative security metrics, and what makes a good metric.
20	Z. Dwaikat, F. Parisi-Presicce, "Risky Trust: Risk-Based Analysis of Software Systems," Proceedings of SESS'05, 2005.	Proposes an approach to evaluate the security of a software system in development; security requirements are derived, and a method is given for evaluating the likelihood of requirements violation based on the individual risks of system components.
21	Y. Liu, I. Traore, A. M. Hoole, "A Service-oriented Framework for Quantitative Security Analysis of Software Architectures," Proceedings of 2008 IEEE Asia-Pacific Services Computing Conference, 2008.	Proposes a User System Interaction Effect (USIE) model for systematically deriving and analyzing security concerns in service-oriented architectures. The model is claimed to provide a foundation for software services security metrics, and one such metric is defined and illustrated.
22	Y. Liu, I. Traore, "Properties for Security Measures of Software Products," *Applied Mathematics & Information Sciences*, I(2), pp. 129–156, 2007.	Describes and formalizes properties that characterize security-related internal software attributes; these properties form a framework that can be used to rigorously identify and evaluate new security metrics; this framework is claimed to be sound but not complete; the properties are claimed to be necessary but not sufficient conditions for good security metrics.

TABLE 32.2 (Continued)

No.	Publication	Summary
23	Y. Liu, I. Traore, "UML-based Security Measures of Software Products," Proceedings of International Workshop on Methodologies for Pervasive and Embedded Software (MOMPES'04), 2004.	Proposes the USIE model mentioned above for Table 32.2 (probably first publication of the model) and derives it from UML (Unified Modeling Language) sequence diagrams; this model can be used as a basis for architectural-level security metrics, and as an example, confidentiality metrics are defined based on the model.
24	E. Chew, M. Swanson, K. Stine, N. Bartol, A. Brown, W. Robinson, "Performance Measurement Guide for Information Security," NIST SP 800-55, Revision 1, 2008.	Provides guidelines for developing, selecting, and implementing information system-level and security program-level measures for assessing the implementation, performance, and impact of security controls and other security related activities.
25	"Recommended Security Controls for Federal Information Systems and Organizations," NIST SP 800-53, 2009.	Describes recommended security controls; includes risk assessment as a control; this publication is used by the "Performance Measurement Guide for Information Security" (Table 32.2) as a basis for developing security measures.
26	T. E. Hart, M. Chechik, D. Lie, "Security Benchmarking Using Partial Verification," Proceedings of HotSec 08, 2008.	Proposes quantifying insecurity using the partial results of verification attempts—instrumented code (assertions) is property checked until a failure is found. The aggregate of such failures determines the level of insecurity of the software.
27	T. Maibaum, "Challenges in Software Certification," SQRL Report 59, McMaster University, May 2010.	Considers the requirements of software certification, proposing that certification should be product based, not development process based; considers the Common Criteria (CC) as a possible product-based model for certification; although this paper is on software certification, it is relevant to security metrics in that it describes the elements of the CC that are pertinent to evaluating the security of a software product.

TABLE 32.3 Managing IT Security Risks.

No.	Publication	Summary
1	Andrew Jaquith, *Security Metrics: Replacing Fear, Uncertainty, and Doubt*, Addison-Wesley, 2007.	Discusses security metrics for enterprise application; security metrics applied broadly, not only to computing systems but also to all sorts of enterprise processes.
2	Lance Hayden, *IT Security Metrics: A Practical Framework for Measuring Security & Protecting Data*, McGraw-Hill Osborne Media, June 2010.	Similar to the Jaquith book in its focus on the enterprise; covers security metrics in terms of effectiveness, implementation, operations, compliance, costs, people, organizations; includes four case studies.
3	J. Talbot, M. Jakeman, *Security Risk Management Body of Knowledge*, book, Wiley, 2009.	Describes the security risk management process; discusses the pros and cons of various risk measures, including risks of threats and attacks.
4	G. Stoneburner, A. Goguen, A. Feringa, "Risk Management Guide for Information Technology Systems," NIST SP 800-30, 2002.	Provides a foundation for developing a risk management program; contains definitions and guidelines for assessing and mitigating risks within IT systems.

Managing IT Security Risks

Table 32.3 lists the publications in this category, which treats the management of risks for IT vulnerabilities taking into account the probability and impact of occurrence. Managing risks is a process, made up of (a) identifying the risks, (b) assessing the risks, and (c) reducing the risks to acceptable levels using established procedures. In addition, some of the papers (Table 32.3 [4]) provide guidance

TABLE 32.4 Measuring the Effectiveness of a Security Process.

No.	Publication	Summary
1	Andrew Jaquith, *Security Metrics: Replacing Fear, Uncertainty, and Doubt*, Addison-Wesley, 2007.	Discusses security metrics for enterprise application; security metrics applied broadly, not only to computing systems but also to all sorts of enterprise processes.
2	Lance Hayden, *IT Security Metrics: A Practical Framework for Measuring Security & Protecting Data*, McGraw-Hill Osborne Media, June 2010.	Similar to the Jaquith book in its focus on the enterprise; covers security metrics in terms of effectiveness, implementation, operations, compliance, costs, people, organizations; includes four case studies.
3	D. Chapin, S. Akridge, "How Can Security Be Measured?" *Information Systems Control Journal*, Vol. 2, 2005.	Discusses what is wrong with traditional security metrics, giving characteristics of good metrics; discusses security maturity models with examples.
4	S.S. Alaboodi, "Towards Evaluating Security implementations Using the Information Security Maturity Model (ISMM)," MASc thesis, University of Waterloo, 2007.	Extensions and abstractions of the ISMM are proposed with the goals of using the extended model to identify the security level of implementations as well as promote the optimization of IT and security expenditures.
5	Carnegie-Mellon University, "The Systems Security Engineering Capability Maturity Model (SSE-CMM)—Model Description Document," Version 3, June 15, 2003. Accessed Mar. 16, 2012, at: http://www.sse-cmm.org/model/model.asp	Describes essential characteristics of a sound security engineering process; addresses security engineering activities that span the entire security engineering life cycle, including process metrics; applies to all types and sizes of security engineering organizations, including commercial, government, and academic organizations.
6	R. F. Lentz, "Advanced Persistent Threats & Zero Day Attacks," slide presentation, 2010.	Describes the stages of the Cyber Security Maturity Model, which can be measures of where an organization stands in terms of its security posture.
7	R. F. Lentz, "Cyber Security Maturity Model," slide presentation, 2011.	Describes advanced persistent threats and the stages of the Cyber Security Maturity Model; appears to be an updated version of Table 32.4 [6].

on selecting security controls for mitigating the identified risks. Security risk management metrics serve to:

- quantify the risks,
- calculate the risks using formulas, and
- quantify the effectiveness of the risk management process.

Here, the difference between the first and second points is that "quantify the risks" is not limited to producing numbers (stating that "plan B" is riskier than "plan A"). Note that, currently, the quantifications of risks and the risk management process are applicable to all of IT, including, for example, operations and software development. They do not focus on evaluating the security of a computer system with sufficient detail. Therefore, the papers in this category, in a broad sense, extend beyond the evaluation of the security of a computer system. Papers that use risks in conjunction with system components and metrics to evaluate security (not risk management) have been placed in Table 32.2.

Measuring the Effectiveness of a Security Process

Table 32.4 lists the publications in this category, which cover metrics that evaluate the effectiveness of security processes or show where an organization is at in terms of a security maturity model. Note that security processes usually describe security within an enterprise. On the other hand, a security maturity model can apply to an enterprise, a geographical region, and even a country.

7. SUMMARY

Security metrics provide a quantitative basis for security operations and security-related decision making. They can be used to measure security improvements over time and can therefore show if a series of new investments in security controls is giving better security. Traditional security metrics have been selected haphazardly and have been problematic in that they often targeted aspects of a

computer system that were irrelevant to the question at hand. Security metrics should be based on the ideal characteristics given in Section 3. Security metrics for application in critical areas such as public safety and health care should be scientifically based once scientifically based security metrics are available and mature. Key aspects of starting a security metrics program for an organization include designing the security metrics based on the ideal characteristics and forming a security metrics cross-functional team. An intelligent security dashboard that not only displays alerts but also automatically handles them is an exciting application of security metrics. It appears that current SIEM technology can be a basis for such a dashboard, but more research work is needed. Security metrics publications cover the nature of security metrics, measuring the security of a computer system, managing risk, and measuring the effectiveness of a security process.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Assessments of security properties cannot used to aid different kinds of decision making, such as program planning, resource allocation, and product and service selection.
2. True or False? Security metrics cannot be used during the software development life cycle to eliminate vulnerabilities, particularly during code production, by performing functions such as measuring adherence to secure coding standards, identifying likely vulnerabilities that may exist, and tracking and analyzing security flaws that are eventually discovered.
3. True or False? Monitoring and reporting of the security status or posture of an IT system can be carried out to determine compliance with security requirements (policy, procedures, and regulations), gauge the effectiveness of security controls and manage risk, provide a basis for trend analysis, and identify specific areas for improvement.
4. True or False? A security metric is given the task of measuring the security of the organization, which is undiscernible only when the organization is in a security crisis, thereby defeating the whole point of having the metric in the first place.
5. True or False? A risk assessment lists a number of threats along with the cost to mitigate each threat or risk.

Multiple Choice

1. The intended use of this metric ________________ is to measure the effectiveness of the anti-malware controls.
   - **A.** Number of security incidents and investigations
   - **B.** Cost of security breaches
   - **C.** Number of computer viruses or malware detected
   - **D.** Resources assigned to security functions
   - **E.** Compliance with security policy
2. What presumably measures the effectiveness of security events monitoring?
   - **A.** Resources assigned to security functions
   - **B.** Cost of security breaches
   - **C.** Number of computer viruses or malware detected
   - **D.** Number of security incidents and investigations
   - **E.** Compliance with security policy
3. What metric is intended to measure the true business loss due to security failures?
   - **A.** Cost of security breaches
   - **B.** Resources assigned to security functions
   - **C.** Number of computer viruses or malware detected
   - **D.** Number of security incidents and investigations
   - **E.** Compliance with security policy
4. The intended use of this metric ________________ is to measure the true business cost of running a security program?
   - **A.** Cost of security breaches
   - **B.** Number of security incidents and investigations
   - **C.** Number of computer viruses or malware detected
   - **D.** Resources assigned to security functions
   - **E.** Compliance with security policy
5. What metric is intended to measure the level of compliance or adhesion to security goals?
   - **A.** Cost of security breaches
   - **B.** Number of security incidents and investigations
   - **C.** Number of computer viruses or malware detected
   - **D.** Resources assigned to security functions
   - **E.** Compliance with security policy

Chapter 33

Cyber Forensics

Scott R. Ellis
kCura Corporation

1. WHAT IS CYBER FORENSICS?

Definition: Cyber forensics is the acquisition, preservation, and analysis of electronically stored information (ESI) in such a way that ensures its admissibility for use as either evidence, exhibits, or demonstratives in a court of law.

Rather than discussing at great length what cyber forensics is (the rest of the chapter will take care of that), let's, for the sake of clarity, define what cyber forensics is *not*. It is not an arcane ability to tap into a vast, secret repository of information about every single thing that ever happened on, or to, a computer. Often, it involves handling hardware in unique circumstances and doing things with both hardware and software that are not, typically, things that the makers or manufacturers ever intended (see sidebar: "Angular Momentum").

Not every single thing a user ever did on a computer is 100% knowable beyond a shadow of a doubt or even beyond reasonable doubt. Some things are certainly *knowable* with varying degrees of certainty. and there is nothing that can happen on a computer through the use of a keyboard and a mouse that cannot be replicated with a software program or macro of some sort. It is fitting, then, that many of the arguments of cyber forensics become philosophical, and that *degrees of certainty* exist and beg definition. Such as: How heavy is the burden of proof? Right away, lest arrogant thoughtlessness prevail, anyone undertaking a study of cyber forensics must understand the core principles of what it means to be in a position of authority and to what varying degrees of certainty an examiner may attest to without finding he has overstepped his mandate (see sidebar, "Angular Momentum"). The sections "Testifying in Court" and "Beginning to End in Court" in this chapter, and the article "Cyber forensics and Ethics, Green Home Plate Gallery View," address these concerns as they relate to ethics and testimonial work.

Angular Momentum

Hard drive platters spin very fast. The 5¼-inch floppy disk of the 1980s has evolved into heavy, metallic platters that spin at ridiculous speeds. If your car wheels turned at 10,000 RPM, you would zip along at 1000 mph. Some hard drives spin at 15,000 RPM. That's really fast. But though HD platters will not disintegrate (as CD-ROMs have been known to do), anecdotal evidence suggests that in larger, heavier drives, the bearings can become so hot that they liquefy, effectively stopping the drive in its tracks. Basic knowledge of surface coating magnetic properties tells us that if the surface of a hard drive becomes overly hot, the basic magnetic properties, the "zeroes and ones" stored by the particulate magnetic domains, will become unstable. The stability of these zeroes and ones maintains the consistency of the logical data stored by the medium. The high speeds of large, heavy hard drives generate heat and ultimately result in drive failure.

Forensic technicians are often required to handle hard drives, sometimes while they have power attached to them. For example, a computer may need to be moved while it still has power attached to it. Here is where a note about angular momentum becomes necessary: A spinning object translates pressure applied to its axis of rotation 90 degrees from the direction of the force applied to it. Most hard drives are designed to park the heads at even the slightest amount of detected g-shock. They claim to be able to withstand thousands of "g's," but this simply means that if the hard drive was parked on a neutron star it would still be able to park its heads. This is a relatively meaningless, static attribute. Most people should understand that if you drop your computer, you may damage the internal mechanics of a hard drive and, if the platters are spinning, the drive may be scored. Older drives, those that are more than three years old, are especially susceptible to damage. Precautions should be taken to keep older drives vibration free and cool.

With very slight, gentle pressures, a spinning hard drive can be handled much as you would handle a gyro and

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00033-7

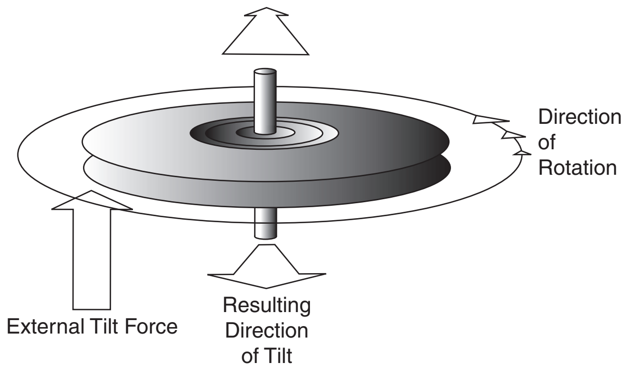

FIGURE 33.1 A spinning object distributes applied force differently than a stationary object. Handle operating hard drives with extreme care.

with little potential for damage. It can be handled in a way that won't cause the heads to park.

Note: Older drives are the exception, and any slight motion at all can cause them to stop functioning.

Most hard drives have piezoelectric shock detectors that will cause the heads to park the instant a certain g-shock value is reached. Piezoelectrics work under the principle that when a force is exerted along a particular axis, certain types of crystals will emit an electrical charge. Just like their pocket-lighter counterparts, they don't always work and eventually become either desensitized or oversensitized; if the internal mechanism of the hard drive is out of tolerance, the shock detector may either work or it won't park the heads correctly and the heads will shred the surface of the platters. Or, if it does work, it may thrash the surface anyway as the heads park and unpark during multiple, repeated shocks. A large, heavy drive (such as a 1 TB drive) will behave exactly as would any heavy disk spinning about an axis—just like a gyro (see Figure 33.1). So, when a vector of force is applied to a drive and it is forced to turn in the same direction as the vector, instead of its natural 90 degree offset, the potential for damage to the drive increases dramatically.

Such is the case of a computer mounted in brackets inside a PC in transit. The internal, spinning platters of the drive try to shift in opposition to the direction the external drive turned; it is an internal tug of war. As the platters attempt to lean forward, the drive leans to the left instead. If there is any play in the bearings at all, the cushion of air that floats the drive heads can be disrupted and the surface of the platters can scratch. If you must move a spinning drive (and sometimes you must), be very careful, go very slowly, and let the drive do all the work. If you must transport a running hard drive, ensure that the internal drive is rotating about the x axis, that it is horizontally mounted inside the computer, and that there is an external shock pad. Some PCs have vertically mounted drives.

Foam padding beneath the computer is essential. If you are in the business of transporting running computers that have been seized, a floating platform of some sort wouldn't be a bad idea. A lot of vibrations, bumps, and jars can shred less durably manufactured HDs. This author once shredded his own laptop hard drive by leaving it turned on, carrying it 15 city blocks, and then for an hour-long ride on the train. You can transport and move computers your entire life and not have an issue. But the one time you do, it could be an unacceptable and unrecoverable loss.

Never move an older computer. If the computer cannot be shut down, then the acquisition of the computer must be completed on site. Any time a computer is to be moved while it's running, everyone involved in the decision-making process should sign off on the procedure and be aware of the risk.

Lesson learned: Always make sure that a laptop put into standby mode has actually gone into standby mode before closing the lid. Windows can be tricky like that sometimes.

2. ANALYSIS OF DATA

Never underestimate the power of a maze. There are two types of mazes that maze experts generally agree on: unicursive and multicursive. In the unicursive maze, the maze has only one answer; you wind along a path and with a little patience you end up at the end. Multicursory mazes, according to the experts, are full of wrong turns and dead ends.

The fact of the matter is, however, when one sets foot into a multicursive maze, one need only recognize that it is, in fact, two unicursory mazes put together, with the path through the maze being the seam. If you take the unicursory tack and simply *always stay to the right (or the left*, as long as you are consistent), you will traverse the entire maze and have no choice but to traverse and complete it successfully.

This is not a section about mazes, but they are analogous in that there are two approaches to cyber forensics: one that churns through every last bit of data and one that takes shortcuts. This is called *analysis*. Quite often as a forensic analyst, the sheer amount of data that needs to be sifted will seem enormous and unrelenting. But there is a path that, if you know it, you can follow it through to success. Here are a few guidelines on how to go about conducting an investigation. For starters, we talk about a feature that is built into most forensic toolsets. It allows the examiner to "reveal all" in a fashion that can place hundreds of thousands of files at the fingertips for examination. It can also create a bad situation, legally and ethically.

Cyber Forensics and Ethics, Green Home Plate Gallery View[1]

A simplified version of this article was published on the Chicago Bar Association blog in late 2007. This is the original version, unaltered.

1. "Cyber forensics and ethics," Green Home Plate Gallery View, Chicago Bar Association Blog, September 2007.

EnCase is a commonly used forensic software program that allows a cyber forensic technologist to conduct an investigation of a forensic hard disk copy. One of the functions of the software is something known as "green-home-plate-gallery-view." This function allows the forensic technologist to create, in *plain view*, a gallery of every single image on the computer.

In EnCase, the entire folder view structure of a computer is laid out just as in Windows Explorer with the exception that to the left of every folder entry are two boxes. One is shaped like a square, and the other like a little "home plate" that turns green when you click on it; hence the "green-home-plate." The technical name for the home plate box is "Set Included Folders." With a single click, every single file *entry* in that folder and its subfolders becomes visible in a table view. An additional option allows the examiner to switch from a table view of entries to a gallery view of *thumbnails*. Both operations together create the "green-home-plate-gallery-view" action.

With two clicks of the mouse, the licensed EnCase user can gather up every single image that exists on the computer and place it into a single, scrollable, thumbnail gallery. In a court-ordered investigation where the search may be for text-based documents such as correspondence, green-home-plate-gallery-view has the potential of being *misused* to visually search the computer for imaged/scanned documents. I emphasize *misused* because, ultimately, this action puts every single image on the computer in *plain view*. It is akin to policemen showing up for a domestic abuse response with an x-ray machine in tow and x-raying the contents of the whole house.

Because this action enables one to view every single image on a computer, including those that may not have anything to do with the forensic search at hand, it raises a question of ethics, and possibly even legality. Can a forensic examiner green-home-plate-gallery-view without reasonable cause?

In terms of a search where the search or motion specifically authorized searching for text-based "documents," green-home-plate-gallery-view is not the correct approach, nor is it the most efficient. The action exceeds the scope of the search and it may raise questions regarding the violation of rights and/or privacy. To some inexperienced examiners, it may seem to be the quickest and easiest route to locating all the documents on a computer. More experienced examiners may use it as a quick litmus test to "peek under the hood" to see if there are documents on the computer.

Many documents that are responsive to the search may be in the form of image scans or PDFs. Green-home-plate-gallery-view renders them visible and available, just for the scrolling. Therein lies the problem: If anything incriminating turns up, it also has the ring of truth in a court of law when the examiner suggests that he was innocently searching for financial documents when he inadvertently discovered, in *plain view*, offensive materials that were outside the scope of his original mandate. But just because something has the ring of truth does not mean that the bell's been rung.

For inexperienced investigators, green-home-plate-gallery-view (see Figure 33.2) may truly seem to be the only recourse and it may also be the one that has yielded the most convictions. However, because there is a more efficient method to capture and detect text, one that can protect privacy and follows the constraints of the search mandate, it should be used.

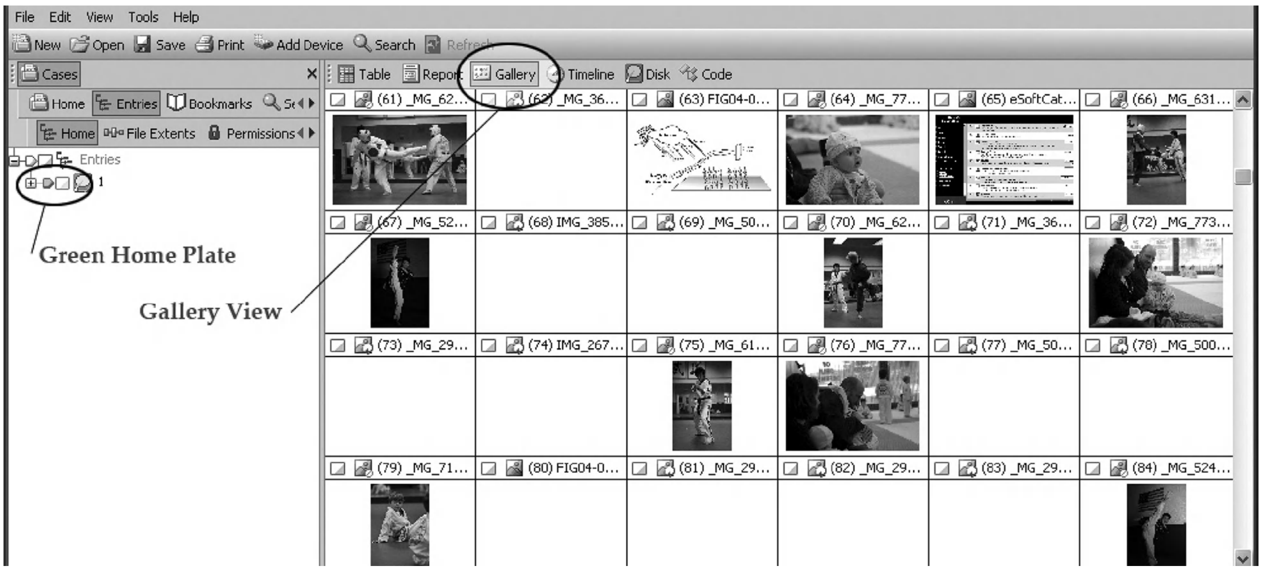

FIGURE 33.2 Green-home-plate-gallery-view.

Current forensic technology allows us, through electronic file signature analysis, sizing, and typing of images, to capture and export every image from the subject file system. Next, through optical character recognition (OCR), the experienced professional can detect every image that has text and discard those that do not. In this manner, images are protected from being viewed, the subject's privacy is protected, and all images with text are located efficiently. The resultant set can then be hashed and reintroduced into EnCase as single files, hashed, and indexed so that the notable files can be bookmarked and a report generated.

Technically, this is a more difficult process because it requires extensive knowledge of imaging, electronic file signature analysis, automated OCR discovery techniques, and hash libraries. But to a trained technician, this is actually faster than green-home-plate-gallery-view, which may yield thousands of images and may take hundreds of hours to accurately review.

In practice, the easiest way is seldom the most ethical way to solve a problem; neither is it always the most efficient method of getting a job done. Currently, there are many such similar scenarios that exist within the discipline of cyber forensics. As the forensic technology industry grows and evolves, professional organizations may eventually emerge that will provide codes of ethics and some syncretism in regard to these issues. For now, however, it falls on attorneys to retain experienced cyber forensic technologists who place importance on developing appropriate ethical protocols. Only when these protocols are in place can we successfully understand the breadth and scope of searches and prevent possible violations of privacy.

Database Reconstruction

A disk that hosts an active database is a very busy place. Again and again throughout this chapter, a single recurring theme will emerge: Data that has been overwritten cannot, by any conventionally known means, be recovered. If it could be, then Kroll Ontrack and every other giant in the forensics business would be shouting this service from the rooftops and charging a premium price for it. Experimentally, accurate statistics on the amount of data that will be overwritten by the seemingly random action of a write head may be available, but most likely it functions by rules that are different for every system based on the amount of usage, the size of the files, and the size of the unallocated clusters. Anecdotally, the formula goes something like this; the rules change under any given circumstances, but this story goes a long way toward telling how much data will be available:

On a server purposed with storing surveillance video, there are three physical hard drives. Drive C serves as the operating system (OS) disk and program files disk; Drives E and F, 350 gigabytes (GB) each, serve as storage disks. When the remote DVR units synchronize each evening, every other file writes to every other disk of the two storage drives. Thirty-day-old files automatically get deleted by the synchronization tool.

After eight months of use, the entire unallocated clusters of each drive, 115 GB on one drive and 123 GB on the other, are completely filled with MPG data. An additional 45 GB of archived deleted files are available to be recovered from each drive.

In this case, the database data were MPG movie files. In many databases, the data, the records (as the database indexes and grows and shrinks and is compacted and optimized), will grow to populate the unallocated clusters. Database records found in the unallocated clusters are not an indicator of deleted records. Database records that exist in the unallocated clusters that don't exist in the live database *are* a sign of deleted records.

Lesson learned: Don't believe everything you see. Check it out and be sure. Get second, third, and fourth opinions when you're uncertain.

3. CYBER FORENSICS IN THE COURT SYSTEM

Cyber forensics is one of the few cyber-related fields in which the practitioner will be found in the courtroom on a given number of days of the year. With that in mind, the following sections are derived from the author's experiences in the courtroom, the lessons learned there, and the preparation leading up to giving testimony. To most lawyers and judges, cyber forensics is a mysterious black art. It is as much a discipline of the art to demystify and explain results in plain English as it is to conduct an examination. It was with special consideration of the growing prevalence of the use of electronically stored information (ESI) in the courtroom, and the general unfamiliarity with how it must be handled as evidence, that spawned the idea for the sidebar "Preserving Digital Evidence in the Age of eDiscovery."

Preserving Digital Evidence in the Age of eDiscovery[2]

Society has awoken in these past few years to the realities of being immersed in the digital world. With that, the harsh realities of how we conduct ourselves in this age of binary processing are beginning to take form in terms of both new laws and new ways of doing business. In many actions, both civil and criminal, digital documents are the new "smoking gun." And with the new Federal laws that

2. Scott R. Ellis, "Preserving digital evidence in the age of ediscovery," *Daily Southtown*, 2007.

open the floodgates of accessibility to your digital media, the sanctions for mishandling such evidence become a fact of law and a major concern.

At some point, most of us (any of us) could become involved in litigation. Divorce, damage suits, patent infringement, intellectual property theft, and employee misconduct are just some examples of cases we see. When it comes to digital evidence, most people simply aren't sure of their responsibilities. They don't know how to handle the requests for and subsequent handling of the massive amounts of data that can be crucial to every case. Like the proverbial smoking gun, "digital evidence" must be handled properly.

Recently, a friend forwarded us an article about a case ruling in which a routine email exhibit was found inadmissible due to authenticity and hearsay issues. What we should take away from that ruling is that electronically stored information (ESI), just like any other evidence, must clear standard evidentiary hurdles. Whenever ESI is offered as evidence, the following evidence rules must be considered.

In most courts, there are four types of evidence. Cyber files that are extracted from a subject machine and presented in court typically fall into one or more of these types:

- *Documentary evidence* is paper or digital evidence that contains human language. It must meet the authenticity requirements outlined below. It is also unique in that it may be disallowed if it contains hearsay. Emails fall into the category of documentary evidence.
- *Real evidence* must be competent (authenticated), relevant, and material. For example, a computer that was involved in a court matter would be considered real evidence provided that it hasn't been changed, altered, or accessed in a way that destroyed the evidence. The ability to use these items as evidence may be contingent on this fact, and that's is why preservation of a cyber or digital media must be done.
- *Witness testimony*. With ESI, the technician should be able to verify how he retrieved the evidence and that the evidence is what it purports to be, and he should be able to speak to all aspects of computer use. The witness must both remember what he saw and be able to communicate it.
- *Demonstrative evidence* uses things like PowerPoint, photographs, or cyber-aided design (CAD) drawings of crime scenes to demonstrate or reconstruct an event. For example, a flowchart that details how a person goes to a Web site, enters her credit-card number, and makes a purchase would be considered demonstrative.

For any of these items to be submitted in court, they each must, to varying degrees, pass the admissibility requirements of relevance, materiality, and competence. For evidence to be *relevant*, it must make the event it is trying to prove either more or less probable. A forensic analyst may discover a certain Web page on the subject hard drive that shows the subject visited a Web site where flowers are sold and that he made a purchase. In addition to perhaps a credit-card statement, this shows that it is more probable that the subject of an investigation visited the site on his computer at a certain time and location.

Materiality means that something not only proves the fact (it is relevant to the fact that it is trying to prove) but is also *material* to the issues in the case. The fact that the subject of the investigation purchased flowers on a Web site may not be material to the matter at hand.

Finally, *competency* is the area where the forensic side of things becomes most important. Assuming that the purchase of flowers from a Web site is material (perhaps it is a stalking case), how the evidence was obtained and what happened to it after that will be put under a microscope by both the judge and the party objecting to the evidence. The best evidence collection experts are trained professionals with extensive experience in their field. The best attorneys will understand this and will use experts when and where needed. Spoliation results from mishandled ESI, and spoiled data is generally inadmissible. It rests upon everyone involved in a case—IT directors, business owners, and attorneys—to get it right. Cyber forensics experts cannot undo damage that has been done, but if involved in the *beginning*, they can prevent it from happening.

4. UNDERSTANDING INTERNET HISTORY

Of the many aspects of user activity, the Internet history is usually of the greatest interest. In most investigations, people such as HR, employers, and law enforcement seek to understand the subject's use of the Internet. What Web sites did he visit? When did he visit them? Did he visit them more than once? The article "What Have You Been Clicking On" (see sidebar) seeks to demystify the concept of temporary Internet files (TIF).

What Have You Been Clicking On?

You've probably heard the rumor that whenever you click on something on a Web page, you leave a deeply rooted trail behind you for anyone (with the right technology) to see. In cyber forensics, just like in archeology, these pieces that a user leaves behind are called *artifacts*. An artifact is a thing made by a human. It tells the story of a behavior that happened in the past.

On your computer, that story is told by metadata stored in databases as well as by files stored on your local machine. They reside in numerous places, but this article will address just three: Internet history, Web cache, and temporary Internet files (TIF). Because Internet Explorer (IE) was developed in a time when bandwidth was precious, storing data locally prevents a browser from having to retrieve the same data every time the same Web page is visited. Also, at the time, no established technology existed that, through a Web browser, could show data on a local

machine without first putting the file on the local machine. A Web browser, essentially, was a piece of software that combined FTP and document-viewing technology into one application platform, complete with its own protocol, HTTP.

In IE, press **Ctrl + H** to view your history. This will show a list of links to all the sites that were viewed over a period of four weeks. The history database only stores the name and date the site was visited. It holds no information about files that may be cached locally. That's the job of the Web cache.

To go back further in history, an Internet history viewer is needed. A Google search for "history.dat viewer" will turn up a few free tools.

The Web cache database, index.dat, is located in the TIF folder; it tracks the date, the time the Web page downloaded, the original Web page filename, and its local name and location in the TIF. Information stays in the index.dat for a long time, much longer than four weeks. You will notice that if you set your computer date back a few weeks and then press **Ctrl + H**, you can always pull the last four weeks of data for as long as you have had your computer (and not cleared your cache). Using a third-party viewer to view the Web cache shows you with certainty the date and origination of a Web page. The Web cache is a detailed inventory of everything in the TIF. Some history viewers will show Web cache information, too.

The TIF is a set of local folders where IE stores Web pages your computer has downloaded. Typically, the size varies depending on user settings. But Web sites are usually small, so 500 MB can hold thousands of Web pages and images! Viewing these files may be necessary. Web mail, financial, and browsing interests are all stored in the TIF. However, malicious software activity, such as pop-ups, exploits, viruses, and Trojans, can cause many strange files to appear in the TIF. For this reason, files that are in the TIF should be compared to their entry in the Web cache. Time stamps on files in the TIF may or may not accurately show when a file was written to disk. System scans periodically alter Last Accessed and Date Modified time stamps! Because of hard-disk caching and delayed writing, the Date Created time stamp may not be the actual time the file arrived. Cyber forensics uses special tools to analyze the TIF, but much is still left to individual interpretations.

Inspection of all the user's Internet artifacts, when intact, can reveal what a user was doing and whether or not a click trail exists. Looking just at time stamps or IE history isn't enough. Users can easily delete IE history, and time stamps aren't always accurate. Missing history can disrupt the trail. Missing Web cache entries or time stamp—altering system scans can destroy the trail. Any conclusions are best not preceded by a suspended leap through the air (you may land badly and trip and hurt yourself). Rather, check for viruses and bad patching, and get the artifacts straight. If there is a click trail, it will be revealed by the Web cache, the files in the TIF, and the history. Bear in mind that when pieces are missing, the reliability of the click trail erodes, and professional examination may be warranted.

5. TEMPORARY RESTRAINING ORDERS AND LABOR DISPUTES

A temporary restraining order (TRO) will often be issued in intellectual property or employment contract disputes. The role of the forensic examiner in a TRO may be multifold, or it may be limited to a simple, one-time acquisition of a hard drive. Often when an employee leaves an organization under less than amicable terms, accusations will be fired in both directions and the resulting lawsuit will be a many-headed beast. Attorneys on both sides may file motions that result in forensic analysis of emails, user activity, and possible contract violations as well as extraction of information from financial and customer relationship management (CRM) databases.

Divorce

Typically the forensic work done in a divorce case will involve collecting information about one of the parties to be used to show that trust has been violated. Dating sites, pornography, financial sites, expatriate sites, and email should be collected and reviewed.

Patent Infringement

When one company begins selling a part that is patented by another company, a lawsuit will likely be filed in federal court. Subsequently, the offending company will be required to produce all the invoices relating to sales of that product. This is where a forensic examiner may be required. The infringed-on party may find through their own research that a company has purchased the part from the infringer and that the sale has not been reported. A thorough examination of the financial system will reveal all the sales. It is wise when doing this sort of work to contact the financial system vendor to get a data dictionary that defines all the fields and the purpose of the tables.

Invoice data is easy to collect. It will typically reside in just two tables: a header and a detail table. These tables will contain customer codes that will need to be joined to the customer table, so knowing some SQL will be a great help. Using the database server for the specific database technology of the software is the gold standard for this sort of work. Getting the collection to launch into VMware is the platinum standard, but sometimes an image won't want to boot. Software utilities such as Live View do a great job of preparing the image for deployment in a virtualized environment.

When to Acquire, When to Capture Acquisition

When a forensics practitioner needs to capture the data on a hard disk, he/she does so in a way that is forensically sound. This means that, through any actions on the part of the examiner, no data on the hard drive is altered and a complete and total copy of the surface of the hard drive platters is captured. Here are some common terms used to describe this process:

- Collection
- Mirror
- Ghost
- Copy
- Acquisition

Any of these terms is sufficient to describe the process. The one that attorneys typically use is *mirror* because they seem to understand it best. A "forensic" acquisition simply means that the drive was write-protected by either a software or hardware write blocker while the acquisition was performed.

Acquisition of an entire hard drive is the standard approach in any case that will require a deep analysis of the behaviors and activities of the user. It is not always the standard procedure. However, most people will agree that a forensic procedure must be used whenever information is copied from a PC. Forensic, enterprise, and ediscovery cases all vary in their requirements for the amount of data that must be captured. In discovery, much of what is located on a computer may be deemed "inaccessible," which is really just fancy lawyer talk for "it costs too much to get it." Undeleting data from hundreds of computers in a single discovery action in a civil case would be a very rare thing to happen and would only take place if massive malfeasance was suspected. In these cases, forensic creation of logical evidence files allows the examiner to capture and copy relevant information without altering the data.

Creating Forensic Images Using Software and Hardware Write Blockers

Both software and hardware write blockers are available. Software write blockers are versatile and come in two flavors. One is a module that "plugs" into the forensic software and can generally be used to write block any port on the computer. The other method of software write blocking is to use a forensic boot disk. This will boot the computer from the hard drive. Developing checklists that can be repeatable procedures is an ideal way to ensure solid results in any investigation.

Software write blockers are limited by the port speed of the port they are blocking, plus some overhead for the write-blocking process. But then, all write blockers are limited in this manner.

Hardware write blockers are normally optimized for speed. Forensic copying tools such as Logicube and Tableau are two examples of hardware write blockers, though there are many companies now that make them. LogiCube will both hash and image a drive at a rate of about 3 GB a minute. They are small and portable and can replace the need for bulky PCs on a job site. There are also appliances and large enterprise software packages that are designed to automate and alleviate the labor requirements of large discovery/disclosure acquisitions that may span thousands of computers.

Live Capture of Relevant Files

Before conducting any sort of a capture, all steps should be documented and reviewed with counsel before proceeding. Preferably, attorneys from both sides on a matter and the judge agree to the procedure before it is enacted. Whenever a new procedure or technique is introduced late on the job site, if there are auditors or observers present, the attorneys will argue, which can delay the work by several hours. Most forensic software can be loaded to a USB drive and launched on a live system with negligible forensic impact to the operating environment. Random Access Memory (RAM) captures are becoming more popular; currently this is the only way to capture an image of physical RAM. Certain companies are rumored to be creating physical RAM write blockers. Launching a forensic application on a running system will destroy a substantial amount of physical RAM as well as the paging file. If either RAM or the paging file is needed, the capture must be done with a write blocker.

Once the forensic tool is launched, either with a write blocker or on a live system, the local drive may be previewed. The examiner may only be interested in Word documents, for example. Signature analysis is a lengthy process in preview mode, as are most searches. A better method, if subterfuge is not expected: Filtering the table pane by extension produces a list of all the docs. "Exporting" them will damage the forensic information, so instead you need to create a logical evidence file (LEF). Using EnCase, a user can create a condition to view all the .DOC files and then dump the files into a logical evidence file in about 30 seconds. Once the logical evidence file is created, it can later be used to create a CD-ROM. There are special modules available that will allow an exact extraction of native files to CD to allow further processing for a review tool.

Redundant Array of Independent (or Inexpensive) Disks (RAID)

Acquiring an entire RAID set disk by disk and then reassembling them in EnCase is probably the easiest way of dealing with a RAID and may be the only way to capture a software RAID. Hardware RAIDs can be most efficiently captured using a boot disk. This allows the capture of a single volume that contains all the unique data in an array. It can be trickier to configure and as with everything, practice makes perfect. Be sure you understand how it works. The worst thing that can happen is that the wrong disk or an unreadable disk gets imaged and the job has to be redone at your expense.

File System Analyses

FAT12, FAT16, and FAT32 are all types of file systems. Special circumstances aside, most forensic examiners will find themselves regularly dealing with either FAT or NTFS file systems. FAT differs from NTFS primarily in the way that it stores information about how it stores information. Largely, from the average forensic examiner's standpoint, very little about the internal workings of these file systems is relevant. Most modern forensic software will do the work of reconstructing and extracting information from these systems, at the system level, for you. Nonetheless, an understanding of these systems is critical because, at any given time, an examiner *just might* need to know it. The following are some examples showing where you might need to know about the file system:

- Rebuilding RAID arrays
- Locating lost or moved partitions
- Discussions of more advanced information that can be gleaned from entries in the MFT or FAT

The difference between FAT12, 16, and 32 is in the size of each item in the File Allocation Table (FAT). Each has a correspondingly sized entry in the FAT. For example, FAT12 has a 12-bit entry in the FAT. Each 12-bit sequence represents a cluster. This places a limitation on the file system regarding the number of file extents available to a file. The FAT stores the following information:

- Fragmentation
- Used or unused clusters
- A list of entries that correspond to each cluster on the partition
- Marks a cluster as used, reserved, unused, or bad
- The cluster number of the next cluster in the chain

Sector information is stored in the directory. In the FAT file system, directories are actually files that contain as many 32-byte slots as there are entries in the folder. This is also where deleted entries from a folder can be discovered. Figure 33.3 shows how the sector view is represented by a common forensic analysis tool.

NTFS

NTFS is a significant advancement in terms of data storage. It allows for long filenames, almost unlimited storage, and a more efficient method of accessing information. It also provides for much greater latency in deleted files, that is, deleted files stick around a lot longer in NTFS than they do in FAT. The following items are unique to NTFS. Instead of keeping the filenames in folder files, the entire file structure of NTFS is retained in a flat file database called the Master File Table (MFT):

- Improved support for metadata
- Advanced data structuring improves performance and reliability
- Improved disk space utilization with a maximum disk size of 7.8 TB, or 2^{64} sectors; sector sizes can vary in NTFS and are most easily controlled using a third-party partitioning tool such as Partition Magic.
- Greater security

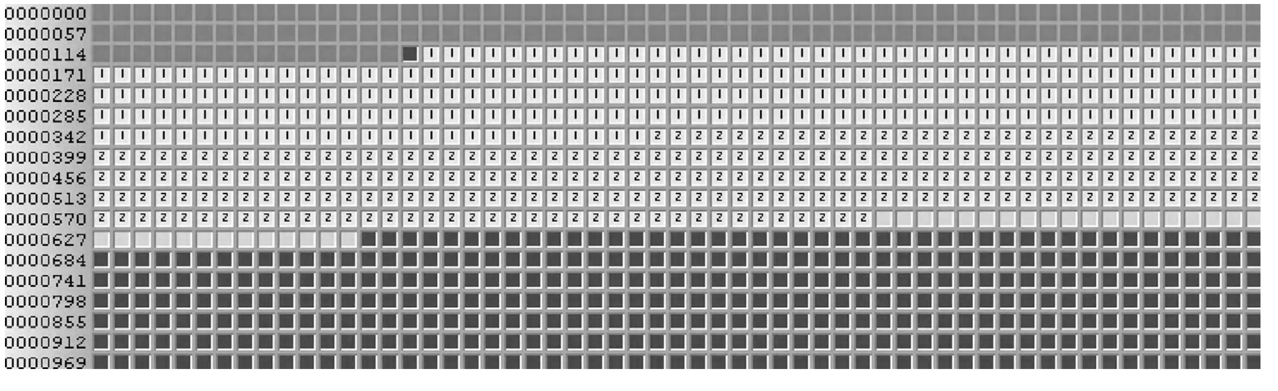

FIGURE 33.3 The sector view.

The Role of the Forensic Examiner in Investigations and File Recovery

The forensic examiner is at his best when he is searching for deleted files and attempting to reconstruct a pattern of user behavior. The sidebar "Oops! Did I Delete That?" first appeared in the Chicago *Daily Southtown* column "Bits You Can Use." In addition, this section also includes a discussion of data recovery and an insurance investigation article (see sidebar, "Don't Touch That Computer! Data Recovery Following Fire, Flood, or Storm").

Oops! Did I Delete That?

The file is gone. It's not in the recycle bin. You've done a complete search of your files for it, and now the panic sets in. It's vanished. You may have even asked people to look through their email because maybe you sent it to them (you didn't). Oops. Now what?

Hours, days, maybe even years of hard work seem to be lost. Wait! Don't touch that PC! Every action you take on your PC at this point may be destroying what is left of your file. It's not too late yet. You've possibly heard that things that are deleted are never really deleted, but you may also think that it will cost you thousands of dollars to recover deleted files once you've emptied the recycle bin. Suffice it to say, unless you are embroiled in complicated ediscovery or forensic legal proceedings where preservation is a requirement, recovering some deleted files for you may cost no more than a tune-up for your car.

Now the part where I told you: "Don't touch that PC!" I meant it. Seriously: Don't touch that PC. The second you realize you've lost a file, stop doing anything. Don't visit any Web sites. Don't install software. Don't reformat your hard drive, do a Windows repair, or install undelete software. In fact, if it's not a server or running a shared database application, pull the plug from the back of the PC. Every time you "write" to your hard drive, you run the risk that you are destroying your lost file. In the case of one author we helped, ten years of a book were "deleted." With immediate professional help, her files were recovered.

Whether you accidentally pulled your USB drive from the slot without stopping it first (corrupting your MFT), intentionally deleted it, or have discovered an "OS not found" message when you booted your PC, you need your files back and you need them now. However, if you made the mistake of actually overwriting a file with a file that has the same name and thereby replaced it, "Abandon hope all ye who enter here." Your file is trashed, and all that may be left are some scraps of the old file, parts that didn't get overwritten but can be extracted from file slack. If your hard drive is physically damaged, you may also be looking at an expensive recovery.

Here's the quick version of how deleted files become "obliterated" and unrecoverable:

Step 1: The MFT that contains a reference to your file marks the deleted file space as available.

Step 2: The actual sectors where the deleted file resides *might* be either completely or partially overwritten.

Step 3: The MFT record for the deleted file is overwritten and destroyed. Any ability to *easily* recover your deleted file at this point is lost.

Step 4: The sectors on the PC that contain your deleted file *are* overwritten and eventually only slight traces of your lost file remain. Sometimes the MFT record may be destroyed before the actual sectors are overwritten. This happens a lot, and these files are recoverable with a little extra work.

It's tremendously amazing how fast this process can occur. It's equally amazing how slowly this process can occur. Recently I retrieved hundreds of files from a system that had periodically been deleting files, and new files were written to the disk on a daily basis. Yet recovery software successfully recovered hundreds of complete files from nearly six months ago! A lot of free space on the disk contributed to this success. A disk that is in use and is nearly full will be proportionally less likely to contain old, deleted files.

The equipment and training investment to perform these operations is high, so expect that labor costs will be higher, but you can also expect some degree of success when attempting to recover files that have been accidentally deleted. Let me leave you with two dire warnings: Disks that have experienced surface damage (scored platters) are unrecoverable with current technology. And never, ever, ever disrupt power to your PC when it's performing a defrag. The results are disastrous.

Don't Touch That Computer! Data Recovery Following Fire, Flood, or Storm

Fire, flood, earthquakes, landslides, and other catastrophes often result in damaged cyber equipment—and loss of electronic data. For claims managers and adjusters, this data loss can manifest itself in an overwhelming number of insurance claims, costing insurers millions of dollars each year.

The improper handling of computers immediately following a catastrophic event is possibly one of the leading causes of data loss—and once a drive has been improperly handled, the chances of data retrieval plummet. Adjusters often assume a complete loss when, in fact, there are methods that can save or salvage data on even the most damaged computers.

Methods to Save or Salvage Data

One of the first steps toward salvaging cyber data is to focus on the preservation of the hard drive. Hard drives are highly precise instruments, and warping of drive components by even fractions of a millimeter will cause damage to occur in the very first moments of booting up. During these moments the drive head can shred the surface of the platters, rendering the data unrecoverable.

Hard drives are preserved in different ways, depending on the damaging event. If the drive is submerged in a

flood, the drive should be removed and resubmerged in clean, distilled water and shipped to an expert. It is important that this is done immediately. Hard drive platters that are allowed to corrode after being exposed to water, especially if the drive experienced seepage, will oxidize and data will be destroyed. A professional can completely disassemble the drive to ensure that all of its parts are dry, determine what level of damage has already occurred, and then decide how to proceed with the recovery. Care must always be taken during removal from the site to prevent the drive from breaking open and being exposed to dust.

Fire or Smoke Damage

After a fire or a flood, the hard drive should not be moved and in no circumstances should it be powered up. A certified cyber forensic expert with experience in handling damaged drives should be immediately contacted. Typically, these experts will be able to dismantle the drive and move it without causing further damage. They are able to assess the external damage and arrive at a decision that will safely triage the drive for further recovery steps. Fire-damaged drives should never be moved or handled by laymen.

Shock Damage

Shock damage can occur when someone drops a computer or it is damaged via an automobile accident; in more catastrophic scenarios, shock damage can result when servers fall through floors during a fire or are even damaged by bulldozers that are removing debris. This type of crushing damage often results in bending of the platters and can be extensive. As in fire and flood circumstances, the drive should be isolated and power should not be applied.

A drive that has been damaged by shock presents a unique challenge: from the outside, the computer may look fine. This is typical of many claims involving laptop computers damaged during an automobile collision. If the computer consultant can verify that the drive was powered down at the time the accident occurred, most will be comfortable attempting to power up a drive that has been in a collision, to begin the data capture process. At the first sign of a change in the dynamics of the drive, a head clicking or a drive spinning down, power will be cut from the drive and the restoration will continue in a clean room where the drive will be opened up and protected from harmful dust.

The Importance of Off-Site Cyber Backup

One of the best ways to maximize cyber data recovery efforts is to have off-site cyber backup. For adjusters arriving at the scene, this should be one of the first questions asked. An offsite backup can take many forms. Some involve the use of special data centers that synchronize data constantly. There are companies that provide this service. Other backups, for smaller companies, may be as mundane (but effective) as removing a tape backup of critical data from the site on a daily basis. With proper rotation and several tapes, a complete backup of data is always offsite. Prices for these services vary widely depending on how much data needs to be backed up and how often.

Case Studies

Scenario 1

John ran a home-based IT business. After his home burned down, John posted an insurance claim for a $500,000 loss for lost income, damaged cyber equipment, and lost wages. He also charged the insurance company $60,000 for the three months he spent recovering data from the drives. Because he was only able to recover 25% of the data, he posted an additional claim for the cost of reconstructing the Web sites that he hosted from his home.

For the cyber forensic consultant, this case raised several questions. As an IT professional, John should have known better than to touch the hard drive and attempt to recover any of the data himself. Also, when a claimant intentionally or unintentionally inflicts damage on his or her own property after an event, who is responsible? Through a thorough evaluation of the circumstances and intense questioning of the claimant, the claim was eventually reduced to a substantially smaller amount.

Scenario 2

Sammie's Flowers has 113 retail outlets and one central headquarters where they keep photography, custom software, catalog masters, and the like. There is no offsite backup. Everything is on CD-ROMs or on the hard drive of the company's server.

One night lightning struck the headquarters building and it burned down. An IT appraiser lacking the appropriate cyber forensic skills evaluated the cyber equipment after the fire. No attempts were made to recover data from the hard drives or to start the computers; because of their damaged physical condition, they were simply thrown into a dumpster.

One year later, the insured filed a claim for $37 million. Under the terms of the insured's policy, coverage for valuable papers and business personal property was most pertinent to the case. The policy limit for valuable papers is small and easily reached. The coverage limit for business personal property, on the other hand, *will* cover the $37 million claim—if the court decides that the cyber data that was lost qualifies as "business valuable papers." Though this case is still pending, the cost of resolving this claim could be astronomic, and had a cyber data recovery expert been consulted, the claim amount could have been reduced by millions.

Scenario 3

Alisa, a professional photographer, was in a car accident that damaged her laptop computer. She had been using the PC at a rest stop prior to the accident and later reported to the adjuster that when she booted it up after the accident she heard "a strange clicking and clacking sound." Unfortunately for Alisa, that was the sound of data being destroyed. She posted a $500,000 claim to her insurance company under her business policy—including the cost of 2000 lost images and the cost of equipment, site, model, and agency fees for a one-day photography shoot. Had the PC, which had a noticeable crack in it caused by the accident, been professionally handled, the chances are good

the data could have been recovered and the claim would have been significantly reduced.

Cyber equipment is always at risk of being damaged—whether by flood, fire, lightning, or other catastrophic means. However, damage does not always equal data loss. Indeed, companies and their adjusters can be quick to write off damaged storage media when, in fact, recovery may be possible. By taking the immediate measures of protecting the computers from touch and power and by calling in professional cyber forensic experts to assess the damage, insurers can reap the benefits in reduced claim amounts.

Password Recovery

The following is a short list of the ways and types of passwords that can be recovered. Many useful tools that can be downloaded from the Internet for free will crack open system files that store passwords. Software programs, such as Peachtree (a financial database), Windows 8, certain FTP programs, and the like all store passwords in a way that allows their easy retrieval.

Recovering license keys for software is often an important step in reconstructing or virtualizing a disk image. Like passwords, without a valid license key the software won't work. There are a number of useful programs that can recover software license keys from the registry of a computer that can be found with a quick Google search. Understanding the mind of the user can also be helpful in locating things such as password storage tools or simply thinking to search a computer for the word *password*. Many, many Web sites will pass the password down to a client machine through the Password field in HTML documents. Some developers have wised up to this "feature" and they strip it out before it comes down, but most of them do it on the client side. This means that with the proper intercepting tool, the password can be captured midstream on its way down to the client, before it gets stripped out.

Password cracking can be achieved with a minimal amount of skill and a great deal of patience. Having some idea of what the password is before cracking it will be helpful. You can also purchase both online services as well as software tools that will strip the password right out of a file, removing it completely. Word documents are particularly vulnerable, and zip files are particularly invulnerable. However, there is a method (and a free download) that can figure out the password of a zip file if a sample of a file that is known to be in the zip can be provided.

File Carving

In most investigations, the very first place a file system examination begins is with live files. Live files are those files that still have MFT entries. Link file, trash bin, Outlook Temporary (OLK) folders, recent items, ISO lists, Internet history, TIF, and thumb databases all constitute a discernible, unique pattern of user activity. As such, they hold particular interest. By exploring these files an examiner can make determinations about file origins, the usage of files, the distribution of files, and of course the current location of the files. But sometimes the subject has been very clever and removed all traces of activity. Or the suspect item may be a server, used merely as a repository for the files. Or maybe someone just wants to recover a file that they deleted a long, long time ago (see sidebar, "Oops, Did I Delete That?").

When such need arises, the vast graveyard called the *unallocated clusters* could hold the last hope that the file can be recovered. By searching the unallocated clusters using a search tool designed for such things, and by using a known keyword in the file, one may locate the portion within the unallocated clusters where a file used to reside. Typically, search hits will be stored under a tab or in a particular area of the forensic toolset, and they may be browsed, one by one, along with a small excerpt from the surrounding bits. By clicking on the search hit, another pane of the software window may show a more expanded view of the hit location. If it is a document, with text, then that is great and you may see other words that were also known to have been in the target file. Now, in TV shows like *CSI*, of course the document is always there, and by running some reverse 128-bit decrytion sequencer to an inverted 12-bit decryption sequencer that reloops the hashing algorithm through a 256-bit decompiler by rethreading it into a multiplexing file marker, they can just right click and say "export this" and the file will print out, even if it's not even on the computer that is being examined and never was. (Yes, I made all that up.)

In the real world, more often than not we find that our examinations are spurred and motivated and wholly created by someone's abject paranoia. In these cases, no amount of digging will ever create the evidence that they want to see. That leaves only creative use of time stamps on documents to attempt to create an aroma of guilt about the subject piece. Sometimes we find that even after rooting through 300 GB of unallocated clusters, leaving no stone unturned, the *file just isn't there*. But sometimes, all pessimism aside, we find little bits and pieces of interesting things all salted around throughout the unallocated clusters.

The first place to turn is the automated carvers. By familiarizing ourselves with the hexadecimal patterns of file signatures (and I've provided a nice table for you here), we may view the hex of the unallocated clusters in a hex editor or in the hex pane of the examination tool. Or possibly we already know the type of file. Let's say that we know the type of file because our client told us that they only use Word as their document editor. We

scroll to the beginning of the section of text, which might look like this:

Figure sample file signature
From the text pane view of EnCase:
ĐÏ·à¡ ± á·············· > ···þÿ·········
From the Hex view:
00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 4F 6F 70 73 21 20 20 44 69 64
20 49 20 64 65 6C 65 74 65 20 74 68 61 74 3F 0D 42 79 20 53 63 6F 74 74 20
52 2E 20 45 6C 6C 69 73 0D 73 65 6C 6C 69 73 40 75 73 2E 72 67 6C 2E 63 6F
6D 0D 0D 54 68 65 20 66 69 6C 65 20 69 73 20 67 6F 6E 65 2E 20 20 49 74 92
73 20 6E 6F 74 20 69 6E 20 74 68 65 20 72 65 63 79 63 6C 65 20 62 69 6E 2E
20 59 6F 75 92 76 65 20 64 6F 6E 65 20 61 20 63 6F 6D 70 6C 65 74 65 20 73

Scrolling down in the text pane, we then find the following:

·············· Oops! Did I delete that? By Scott R. Ellis The file is gone. It's not in the recycle bin. You've ....

By simply visually scanning the unallocated clusters, we can pick up where the file begins and, if the file signature isn't in the provided list of signatures or if for some reason the carving scripts in the forensic software are incorrectly pulling files, they may need to be manually set up. Truly, for Word files, that is all you need to know. You need to be able to determine the end and the beginning of a file. Some software will ignore data in the file before and after the beginning and end of file signatures. This is true for many, many file types; I can't tell you which ones because I haven't tried them all. There are some file types that need a valid end-of-file (EOF) marker, but most don't. However, if you *don't* capture the true EOF (sensible marker or no), the file may look like garbage or all the original formatting will be scrambled or it won't open. Some JPEG viewers (such as Adobe Photoshop) will throw an error if the EOF is not found. Others, such as Internet Explorer, won't even notice. Here's the trick—and it is a trick, and don't let anyone tell you differently; they might not teach this in your average university cyber forensics class: Starting with the file signature, highlight as many of the unallocated clusters *after* the file signature that you think would possibly be big enough to hold the entire file size. Now double that, and export it as raw data. Give it a .DOC extension and open it in Word. *Voilá!* The file has been reconstructed. Word will know where the document ends and it will show you that document. If you happen to catch a few extra documents at the end, or a JPG or whatever, Word will ignore them and show only the first document.

Unless some sort of drastic "wiping action" has taken place, as in the use of a third-party utility to delete data, I have almost always found that a great deal of deleted data is *immediately* available in EnCase (forensic software) within 20−25 minutes after a hard disk image is mounted, simply by running "recover folders" and sitting back and waiting while it runs. This is especially true when the drive has not been used at all since the time the data was deleted. Preferably, counsel will have taken steps to ensure that this is the case when a computer is the prime subject of an investigation. Often this is not the case, however. Many attorneys, IT, and HR directors "poke around" for information all on their own.

It is conceivable that up to 80% of deleted data on a computer may be readily available, without the necessity of carving, for up to two or three years, as long as the computer hasn't seen extreme use (large amounts of files, or large amounts of copying and moving of very large files) that could conceivably overwrite the data.

Even so, searching unallocated clusters for file types typically does not require the creation of an index. Depending on the size of the drive, it may take four or five hours for the carving process to complete, and it may or may not be entirely successful, depending on the type of files that are being carved. For example, MPEG videos do not carve well at all, but there are ways around that. DOC and XLS files usually carve out quite nicely.

Indexing is something that is done strictly for the purpose of searching massive amounts of files for large numbers of keywords. We rarely use EnCase to search for keywords; we have found it better to use Relativity, our review environment, to allow the people who are interested in the keywords to do the keyword searching themselves as they perform their review. Relativity is built on an SQL platform on which indexing is a known and stable technology.

In other words (as in the bottom line), spending 15 to 25 minutes with a drive, an experienced examiner can provide a very succinct answer as to how long it would take to provide the files that they want. And, very likely, the answer could be, "Another 30 minutes and it will be yours." Including time to set up, extract, and copy to disk, if everything is in perfect order, two hours is the upper limit. This is based on the foundation that the deleted data they are looking for was deleted in the last couple of weeks of the use of the computer. If they need to go back more than a couple of months, an examiner may end up carving into the unallocated clusters to find "lost" files—these are files for which part of or all of the master file table entry has been obliterated and portions of the files themselves may be overwritten.

Carving is considered one of the consummate forensic skills. Regardless of the few shortcuts that exist, carving requires a deep, disk-level knowledge of how files are

stored, and it requires a certain intuition that cannot be "book taught." Examiners gain this talent from years of looking at raw disk data. Regardless, even the most efficient and skilled of carvers will turn to their automated carving tools. Two things that the carving tools excel at is carving out images and print spool files (EMFs). What are they really bad at? The tools I use don't even begin to work properly to carve out email files. General regular program (GREP) searching doesn't provide for branching logic, so you can't locate a qualified email header, every single time, and capture the end of it. The best you can do is create your own script to carve out the emails. GREP does not allow for any sort of true logic that would be useful or even efficient at capturing something as complex as the many variations of email headers that exist, but it does allow for many alterations of a single search term to be formulated with a single expression. For example, the words *house*, *housing*, *houses*, and *housed* could all be searched for with a single statement such as "hous [(e)|(es)|(ing)|(ed)]". GREP can be useful, but it is not really a shortcut. Each option added to a GREP statement doubles the length of time the search will take to run. Searching for *house(s)* has the same run time as two separate keywords for *house* and *houses*. It also allows for efficient pattern matching. For example, if you wanted to find all the phone numbers on a computer for three particular area codes, you could formulate a GREP expression like this. Using a test file and running the search each time, an expression can be built that finds phone numbers in any of three area codes:

(708)|(312)|(847) Checks for the three area codes
[\(]?(708)|(312)|(847)[\-\)\.]? Checks for parentheses and other formatting
[\(]?(708)|(312)|(847)[\-\)\.]?###[\-\.]?#### Checks for the rest of the number

This statement will find any 10-digit string that is formatted like a phone number, as well as any 10-digit string that contains one of the three area codes. This last option, to check for any 10-digit number string, if run against an entire OS, will likely return numerous results that aren't phone numbers. The question marks render the search for phone number formatting optional.

The following are the characters that are used to formulate a GREP expression. Typically, the best use of GREP is its ability to formulate pattern-matching searches. In GREP, the following symbols are used to formulate an expression:

- . The period is a wildcard and means a space must be occupied by any character.
- * The asterisk is a wildcard that means any character or no character. It will match multiple repetitions of the character as well.
- ? The character preceding the question mark must repeat 0 or 1 times. It provides instructions as to how to search for the character or grouping that precedes it.
- + This is like the question mark, only it *must* exist at least one or more times.
- # Matches a number.
- [·] Matches a list of characters. *[hH]i* matches *hi* and *Hi* (but not *hHi!)*.
- ^ This is a "not" and will exclude a part from a string.
- [-] A range of characters such as (a-z) will find any single letter, a through z.
- \ This will escape the standard GREP search symbols so that it may be included as part of the search. For example, a search string that has the (symbol in it (such as a phone number) needs to have the parentheses escaped so that the string can be included as part of the search.
- | This is an "or." See previous sample search for area codes.
- \x Searches for the indicated hex string.

By preceding a hex character with \x marks the next two characters as hexadecimal characters. Using this to locate a known hex string is more efficient than relying on it to be interpreted from Unicode or UTF.

Most forensic applications have stock scripts included that can carve for you. Many of the popular cyber forensics applications can carve for you. They have scripted modules that will run, and all you have to do is select the signature you want and *voilá*, it carves it right out of the unallocated clusters for you. Sounds pretty slick, and it is slick—when it works. The problem is that some files, such as MPEG video, don't have a set signature at the beginning and end of each file. So how can we carve them? Running an MPEG carver will make a mess. It's a far better thing to do a "carve" by locating MPEG data, highlighting it, exporting it to a file, and giving it an MPEG extension.

Things to Know: How Time Stamps Work

Let's take an example: Bob in accounting has been discovered to be pilfering from the cash box. A forensics examiner is called in to examine his cyber system to see if he has been engaging in any activities that would be against company policy and to see if he has been accessing areas of the network that he shouldn't be. They want to know what he has been working on. A quick examination of his PC turns up a very large cache of pornography. A casual glance at the Entry Modified time stamp shows that the images were created nearly one year before Bob's employment, so automatically the

investigator disregards the images and moves onto his search for evidence of copying and deleting sensitive files to his local machine. The investigator begins to look at the deleted files. His view is filtered, so he is not looking at anything but deleted files. He leaves the view in "gallery" view so that he can see telltale images that may give clues as to any Web sites used during the timeframe of the suspected breaches. To his surprise, the investigator begins seeing images from that porn cache. He notices now that when a deleted file is overwritten, in the gallery view of the software the image that overwrote the deleted file is displayed. He makes the logical conclusion that the Entry Modified time stamp is somehow wrong.

On a Windows XP machine, an archive file is extracted. Entry Modified time stamps are xx:xx:xx, even though the archive was extracted to the file system on yy:yy:yy. Normally when a file is created on a system, it takes on the system date as its Date Created time stamp. Such is not the case with zip files.

Entry Modified, in the world of cyber forensics, is that illustrious time stamp that has cinched many a case. It is a hidden time stamp that users never see, and few of them actually know about it. As such, they cannot change it. A very little-known fact about the Entry Modified time stamp is that it is constrained. It can be no later than the Date Created time stamp. (This is not true in Vista.) When a zip file is created, the Date Created and Date Modified time stamps become the same.

Experimental Evidence

Examining and understanding how time stamps behave on individual PCs and operating systems provide some of the greatest challenges facing forensic examiners. This is not due to any great difficulty, but rather because of the difficulty in clearly explaining it to others. This examiner once read a quote from a prosecutor in a local newspaper that said, "We will clearly show that he viewed the image on three separate occasions." In court the defense's expert disabused her of the notion she held that Last Written, Last Accessed, Entry Modified, and Date Created time stamps were convenient little recordings of user activity. Rather, they are references mostly used by the operating system for its own arcane purposes. Table 33.1 compares the three known Windows time stamps with the four time stamps in EnCase.

XP

A zip file was created using a file with a Date Created time stamp of 12/23/07 10:40:53AM (see ID 1 in Table 19.2). It was then extracted and the time stamps were examined.

Using Windows XP compressed folders, the file was then extracted to a separate file on a different system (ID 2 in Table 33.2). Date Created and Entry Modified time stamps, upon extraction, inherited the original Date Created time stamp of 12/23/12 10:40:53AM and Last Accessed of 04/28/13 01:56:07PM.

TABLE 33.1 Comparison of Three Known Windows Time stamps with the Four EnCase Time Stamps.

Windows	EnCase	Purpose
Date Created	Date Created	Typically this is the first time a file appeared on a system. It is not always accurate.
Date Modified	Last Written	Usually this is the time when a system last finished writing or changing information in a file.
Last Accessed	Last Accessed	This time stamp can be altered by any number of user and system actions. It should not be interpreted as the file having been opened and viewed.
N/A	Entry Modified	This is a system pointer that is inaccessible to users through the Explorer interface. It changes when the file changes size.

TABLE 33.2 Date Created Time Stamp.

ID	Name	Last Accessed	File Created	Entry Modified
1	*IMG_3521.CR2*	*04/28/08 01:56:07PM*	*12/23/07 10:40:53AM*	*03/15/08 09:11:15AM*
2	IMG_3521.CR2	04/28/08 01:56:07PM	12/23/07 10:40:53AM	04/28/08 01:57:12PM

TABLE 33.3 Altering the Entry Modified Time Stamp.

ID	Name	Last Accessed	File Created	Entry Modified
1	*IMG_3521.CR2*	*04/28/08 01:56:07PM*	*12/23/07 10:40:53AM*	*03/15/08 09:11:15AM*
2	IMG_3521.CR2	05/21/08 03:32:01PM	12/23/07 10:40:53AM	05/21/08 03:32:01PM

The system Entry Modified (not to be confused with Date Modified) became 04/28/13 01:57:12PM.

Various operating systems can perform various operations that will, *en masse*, alter the Entry Modified time stamp (see Table 33.3). For example, a tape restoration of a series of directories will create a time stamp adjustment in Entry Modified that corresponds to the date of the restoration. The original file is on another system somewhere and is inaccessible to the investigator (because he doesn't know about it).

In Table 33.3, Entry Modified becomes a part of a larger pattern of time stamps after an OS event. On a computer on which most of the time stamps have an Entry Modified time stamp that is sequential to a specific timeframe, it is now more difficult to determine when the file actually arrived on the system. As long as the date stamps are not inherited from the overwriting file by the overwritten file, examining the files that were overwritten by ID2 (Table 19.3), can reveal a No Later Than time. In other words, the file could not have appeared on the system prior to the file that it overwrote.

Vista

A zip file was created using a file with a Date Created time stamp of dd:mm:yyyy(a) and a date modified of dd:mm:yy(a). Using Windows Vista compressed folders, the file was then extracted to a separate file on the same system. Date Modified time stamps, on extraction, inherited the original time stamp of dd:mm:yyyy(a), but the Date Created time stamp reflected the true date. This is a significant change from XP. There are also tools available that will allow a user to mass-edit time stamps. Forensic examiners must always bear in mind that there are some very savvy users who research and understand antiforensics.

Email Headers and Time Stamps, Email Receipts, and Bounced Messages

There is much confusion in the ediscovery industry and in cyber forensics in general about how best to interpret email time stamps. Though it might not offer the perfect "every case" solution, this section reveals the intricacies of dealing with time stamps and how to interpret them correctly.

Regarding sources of email, SMTP has to relay email to its own domain. HELO/EHLO allows a user to connect to the SMTP port and send email.

As most of us are aware, in 2007 the U.S. Congress enacted the Energy Policy Act of 2005 (http://www.epa.gov/oust/fedlaws/publ_109-058.pdf, Section 110. Daylight Savings). This act was passed into law by President George W. Bush on August 8, 2005. Among other provisions, such as subsidies for wind energy, reducing air pollution, and providing tax breaks to homeowners for making energy-conserving changes to their homes, it amended the Uniform Time Act of 1966 by changing the start and end dates for Daylight Savings Time (DST) beginning in 2007. Previously, clocks would be set ahead by an hour on the first Sunday of April and set back on the last Sunday of October. The new law changed this as follows: Starting in 2007 clocks were set ahead one hour on the first Sunday of March and then set back on the first Sunday in November. Aside from the additional confusion now facing everyone when we review email and attempt to translate Greenwich Mean Time (GMT) to a sensible local time, probably the only true noteworthy aspect of this new law is the extra daylight time afforded to children trick-or-treating on Halloween. Many observers have questioned whether or not the act actually resulted in a net energy savings.

In a world of remote Web-based email servers, it has been observed that some email sent through a Web mail interface will bear the time stamp of the time zone wherein the server resides. Either your server is in the Central Time zone or the clock on the server is set to the wrong time/time zone. Servers that send email mark the header of the email with the GMT stamp numerical value (noted in bold in the example that follows) as opposed to the actual time zone stamp. For example, instead of saying 08:00 CST, the header will say 08:00 (-0600). The GMT differential is used so that every email client interprets that stamp based on the time zone and time setting of itself and is able to account for things like Daylight Savings Time offsets. This is a dynamic interpretation; if I change the time zone of my computer, it will change the way Outlook *shows* me the time of each email, but it doesn't actually physically change the email itself. For

example, if an email server is located in Colorado, every email I send appears to have been sent from the Mountain Time zone. My email client interprets the Time Received of an email based on when my server received the mail, *not* when my email client downloads the email from my server.

If a server is in the Central Time zone and the client is in Mountain Time, the normal Web mail interface will not be cognizant of the client's time zone. Hence those are the times you'll see. I checked a Webmail account on a server in California that I use and it does the same thing. Here I've broken up the header to show step by step how it moved. Here is, first, the entire header in its original context, followed by a breakdown of how I interpret each transaction in the header:

****

Looks like a bunch of garbage, right? Here it is, step by step, transaction by transaction, in reverse chronological order:

1. My server in Colorado receives the email (GMT differential is in bold):

   Received: from p01c11m096.mxlogic.net (208.65.144.247) by mail.us.rgl.com
   (192.168.0.12) with Microsoft SMTP Server id 8.0.751.0; Fri, 30 Nov 2007 21:03:15 -0700

2. Prior to that, my mail-filtering service in Colorado receives the email:

   Received: from unknown [65.54.246.112] (EHLO bay0-omc1-s40.bay0.hotmail.com)
   by p01c11m096.mxlogic.net (mxl_mta-5.2.0-1) with ESMTP id 23cd0574.3307895728.120458.00-105.p01c11m096.
   mxlogic.net (envelope-from
   <timezone3@hotmail.com>); Fri, 30 Nov 2007 20:59:46 -0700 (MST)

   – The email server receives the sender's email in this next section. On most networks, the mail server is rarely the same machine on which a user created the email. This next item in the header of the email shows that the email server is located in the Pacific Time zone. 65.54.246.112, the x-origin stamp, is the actual IP address of the computer that sent the email:

   Received: from BAY108-W37 ([65.54.162.137]) by bay0-omc1-s40.bay0.hotmail.com
   with Microsoft SMTPSVC(6.0.3790.3959); Fri, 30 Nov 2007 19:59:46 ***-0800***
   Message-ID: <BAY108-W374BF59F8292A9D2C95F08BA720@phx.gbl>
   Return-Path: timezone310@hotmail.com

– This content was produced on the server where the Webmail application resides. Technically, the email was created on the Web client application with only one degree of separation between the originating IP and the sender IP. By examining the order and type of IP addresses logged in the header, a trail can be created that shows the path of mail servers that the email traversed before arriving at its destination. This machine is the one that is likely in the Central Time zone, since it can be verified by the -0600 in the following. The X-originating IP address is the IP address of the sender's external Internet connection IP address in her house and the X-Source IP address is the IP address of the Webmail server she logged into on this day. This IP address is also subject to change because they have many Webmail servers as well. In fact, comparisons to older emails sent on different dates show that it is different. Originating IP address is also subject to change since a DSL or cable Internet is very likely a dynamic account, but it (likely) won't change as frequently as the X-source:

Bill and Scott,
By the way, it was 8:57 my time when I sent the last email, however, my hotmail shows that it was 9:57 pm. Not sure if their server is on Central time or not. Scott, can you help with that question? Thanks.

Steganography "Covered Writing"

Steganography tools provide a method that allows a user to hide a file in plain sight. For example, there are a number of stego software tools that allow the user to hide one image inside another. Some of these do it by simply appending the "hidden" file at the tail end of a JPEG file and then add a pointer to the beginning of the file. The most common way that steganography is discovered on a machine is through the detection of the steganography software on the machine. Then comes the arduous task of locating 11 of the files that may possibly contain hidden data. Other, more manual stego techniques may be as simple as hiding text behind other text. In Microsoft Word, text boxes can be placed right over the top of other text, formatted in such a way as to render the text undetectable to a casual observer. Forensic tools will allow the analyst to locate this text, but on opening the file the text won't be readily visible. Another method is to hide images behind other images using the layers feature of some photo enhancement tools, such as Photoshop.

StegAlyzerAS is a tool created by Backbone Security to detect steganography on a system. It works by both searching for known stego artifacts as well as by searching for the program files associated with over 650 steganography toolsets. Steganography hash sets are also available within the NIST database of hash sets. Hash

sets are databases of MD5 hashes of known unique files associated with a particular application.

6. FIRST PRINCIPLES

In science, *first principles* refer to going back to the most basic nature of a thing. For example, in physics, an experiment is *ab initio* (from first principles) if it only subsumes a parameterization of known irrefutable laws of physics. The experiment of calculation does not make assumptions through modeling or assumptive logic.

First principles, or *ab initio*, may or may not be something that a court will understand, depending on the court and the types of cases it tries. Ultimately the very best evidence is that which can be easily duplicated. In observation of a compromised system in its live state, even if the observation photographed or videoed may be admitted as evidence but the events viewed cannot be duplicated, the veracity of the events will easily be questioned by the opposition.

During an investigation of a defendant's PC, an examiner found that a piece of software on the computer behaved erratically. This behavior had occurred after the computer had been booted from a restored image of the PC. The behavior was photographed and introduced in court as evidence. The behavior was mentioned during a cross-examination and had not, originally, been intended as use for evidence; it was simply something that the examiner recalled seeing during his investigation, that the list of files a piece of software would display would change. The prosecution was outraged because this statement harmed his case to a great deal. The instability and erratic behavior of the software was one of the underpinnings of the defense. The examiner, in response to the prosecutor's accusations of ineptitude, replied that he had a series of photographs that demonstrated the behavior. The prosecutor requested the photos, but the examiner didn't have them in court. He brought them the next day, at which time, when the jury was not in the room, the prosecutor requested the photos, reviewed them, and promptly let the matter drop.

It would have been a far more powerful thing to have produced the photographs at the time of the statement; but it may have also led the prosecution to an *ab initio* effort—one that may have shown that the defense expert's findings were irreproducible. In an expert testimony, the more powerful and remarkable a piece of evidence, the more likely it is to be challenged by the opposition. It is an intricate game because such a challenge may ultimately destroy the opposition's case, since a corroborative result would only serve to increase the veracity and reliability of the expert's testimony. Whether you are defense, prosecution, or plaintiff, the strongest evidence is that which is irrefutable and relies on first principles. Aristotle defined it as those circumstances where "for the same (characteristic) simultaneously to belong and not belong to the same (object) in the same (way) is impossible." In less obfuscating, 21st-century terms, the following interpretation is applicable: One thing can't be two different things at the same time in the same circumstance; there is only one truth, and it is self-evidentiary and not open to interpretation. For example, when a computer hard drive is imaged, the opposition may also image the same hard drive. If proper procedures are followed, there is no possible way that different MD5 hashes could result. Black cannot be white.

The lesson learned? Never build your foundation on irreproducible evidence. To do so is tantamount to building the case on "circumstantial" evidence.

7. HACKING A WINDOWS XP PASSWORD

There are many, many methods to decrypt or "hack" a Windows password. This section lists some of them. One of the more interesting methods of cracking passwords through the use of forensic methods is hacking the Active Directory. It is not covered here, but suffice it to say that there is an awesome amount of information stored in the Active Directory file of a domain server. With the correct tools and settings in place, Bitlocker locked PCs can be accessed and passwords can be viewed in plaintext with just a few simple, readily available scripts.

Net User Password Hack

If you have access to a machine, this is an easy thing, and the instructions to do it can easily be found on YouTube. Type **net users** at the Windows command line. Pick a user. Type **net user*username****. (You have to type the asterisk or it won't work.) You will then, regardless of your privileges, be allowed to change any password, including the local machine administrator password.

Lanman Hashes and Rainbow Tables*

- The following procedure can be used to "reverse-engineer" the password from where it is stored in Windows. Lan Manager (or Lanman, or LM) has been used by Windows, in versions prior to Windows Vista, to store passwords that are shorter than 15 characters. The vast majority of passwords are stored in this format. LM hashes are computed via a short series of actions. The following items contribute to the weakness of the hash.
- Password is converted to all uppercase.
- Passwords longer than seven characters are divided into two halves. By visual inspection of the hash, this allows us to determine whether the second half is

padding. We can do this by viewing all the LM hashes on a system and observing whether the second halves of any of the hashes are the same. This will speed up the process of decrypting the hash.

- There is no salt. In cryptography, *salt* is random bits that are thrown in to prevent large lookup tables of values from being developed.

Windows will store passwords using the Lanman hash. Windows Vista has changed this. For all versions of Windows except Vista, about 70 GB of what are called *rainbow tables* can be downloaded from the Internet. Using a tool such as the many that are found on Backtrack will capture the actual hashes that are stored for the password on the physical disk. Analysis of the hashes will show whether or not the hashes are in use as passwords. Rainbow tables, which can be downloaded from the Web in a single 70 GB table, are simply lookup tables of every possible iteration of the hashes. By entering the hash value, the password can be easily and quickly reverse-engineered and access to files can be gained. A favorite method of hackers is to install command-line software on remote machines that will allow access to the Lanman hashes and will send them via FTP to the hacker. Once the hacker has admin rights, he owns the machine.

Password Reset Disk

Emergency Boot CD (EBCD) is a Linux-based tool that allows you to boot a computer that has an unknown password. Using this command-line tool, you can reset the administrator password very easily. It will not tell you the plaintext of the password, but it will clear it so that the machine can be accessed through something like VMware with a blank password.

Memory Analysis and the Trojan Defense

One method of retrieving passwords and encryption keys is through memory analysis—physical RAM. RAM can be acquired using a variety of relatively nonintrusive methods. HBGary.com offers a free tool that will capture RAM with very minimal impact. In addition to extracting encryption keys, RAM analysis can be used to either defeat or corroborate the Trojan defense. The Responder tool from HBGary (single-user license) provides in-depth analysis and reporting on the many malware activities that can be detected in a RAM environment. The Trojan defense is commonly used by innocent and guilty parties to explain unlawful actions that have occurred on their computers. The following items represent a brief overview of the types of things that can be accomplished through RAM analysis:

- A hidden driver is a 100% indicator of a bad guy. Hidden drivers can be located through analysis of the physical memory.
- Using tools such as FileMon, TCPView, and RegMon, you can usually readily identify malware infections. There is a small number of advanced malwares that are capable of doing things such as rolling up completely (poof, it's gone!) when they detect the presence of investigative tools or that are capable of escaping a virtualized host. All the same, when conducting a malware forensic analysis, be sure to isolate the system from the network.
- RAM analysis using a tool such as HBGary's Responder can allow reverse-engineering of the processes that are running and can uncover potential malware behavioral capabilities. As this science progresses, a much greater ability to easily and quickly detect malware can be expected.

User Artifact Analysis

There is nothing worse than facing off against an opposing expert who has not done his artifact analysis on a case. Due to an increasing workload in this field, experts are often taking shortcuts that, in the long run, really make more work for everyone. In life and on computers, the actions people take leave behind artifacts. The following is a short list of artifacts that are readily viewed using any method of analysis:

- Recent files
- OLK files
- Shortcuts
- Temporary Internet Files (TIF)
- My Documents
- Desktop
- Recycle Bin
- Email
- EXIF data

Users create all these artifacts, either knowingly or unknowingly, and aspects of them can be reviewed and understood to indicate that certain actions on the computer took place—for example, a folder in My Documents called "fast trains" that contains pictures of Europe's TGV and surrounding countryside, TIF sites that show the user booking travel to Europe, installed software for a Casio Exilim digital camera, EXIF data that shows the photos were taken with a Casio Exilim, and email confirmations and discussions about the planned trip all work together to show that the user of that account on that PC did very likely take a trip to Europe and did take the photos. Not that there is anything wrong with taking pictures of trains, but if the subject of the investigation is a suspected terrorist and he has ties

with a group that was discovered to be planning an attack on a train, this evidence would be very valuable.

It is the sum of the parts that matters the most. A single image of a train found in the user's TIF would be virtually meaningless. Multiple pictures of trains in his TIF could also be meaningless; maybe he likes trains or maybe someone sent him a link that he clicked to take him to a Web site about trains. *It's likely he won't even remember having visited the site*. It is the forensic examiner's first priority to ensure that all the user artifacts are considered when making a determination about any behavior.

Recovering Lost and Deleted Files

Unless some sort of drastic "wiping action" has taken place, as in the use of a third-party utility to delete data or if the disk is part of a RAIDed set, I have almost always found that deleted data is *immediately* available in EnCase (forensic software I use) within 20 to 25 minutes after a hard disk image is mounted. This is especially true when the drive has not been used at all since the time the data was deleted.

Software Installation

Nearly every software installation will offer to drop one on your desktop, in your Start menu, and on your quick launch tool bar at the time of program installation. Whenever a user double-clicks on a file, a link file is created in the Recent folder located at the root of Documents and Settings. This is a hidden file.

Recent Files

In Windows XP (and similar locations exist in other versions), link files are stored in the Recent folder under Documents and Settings. Whenever a user double-clicks on a file, a link file is created. Clicking the Start button in Windows and navigating to the My Recent Documents link will show a list of the last 15 documents that a user has clicked on. What most users don't realize is that the C:\Documents and Settings\$user name$\Recent folder will potentially reveal *hundreds* of documents that have been viewed by the user. This list is indisputably a list of documents that the user has viewed. Interestingly, in Windows 2000, if the Preserve History feature of the Windows Media Player is turned off, no link files will be created. The only way to make any legitimate determination about the use of a file is to view the Last Accessed time, which has been shown in several cases to be inconsistent and unreliable in certain circumstances. Be very careful when using this time stamp as part of your defense or prosecution. It is a loaded weapon, ready to go off.

Start Menu

The Start menu is built on shortcuts. Every item in the Start file has a corresponding .LNK file. Examining Last Accessed or Date Created time stamps may shed light on when software was installed and last used.

Email

Extracting email is an invaluable tool for researching and finding out thoughts and motives of a suspect in any investigation. Email can be extracted from traditional client-based applications such as Outlook Express, Lotus Notes, Outlook, Eudora, and Netscape Mail as well as from common Webmail apps such as Gmail, Hotmail, Yahoo Mail, and Excite. Reviewing log files from server-based applications such as Outlook Webmail can show a user, for example, accessing and using his Webmail after employment termination. It is important that companies realize that they should terminate access to such accounts the day a user's employment is terminated.

Internet History

Forensic analysis of a user's Internet history can reveal much useful information. It can also show the exact code that may have downloaded on a client machine and resulted in an infection of the system with a virus. Forensic examiners should actively familiarize themselves with the most recent, known exploits.

Typed URLs is a registry key. It will store the last 10 addresses that a user has typed into a Web browser address field. I once had a fed try to say that everything that appeared in the drop-down window was a "typed" URL. This is not the case. The only definitive source of showing the actual typed URLs is the registry key. Just one look at the screen shown in Figure 33.4 should clearly demonstrate that the user never would have "typed" all these entries. Yet that is exactly what a Department of Homeland Security Agent sat on the witness stand and swore, under oath, was true. In Figure 33.4, simply typing in **fil** spawns a list of URLs that were never typed but rather are the result of either the user having opened a file or a program having opened one. The highlighted file entered the history shown as a result of installing the software, not as a result of the user "typing" the filename. Many items in the history wind their way into it through regular software use, with files being accessed as an indirect result of user activity.

8. NETWORK ANALYSIS

Many investigations require a very hands-off approach in which the only forensics that can be collected is network

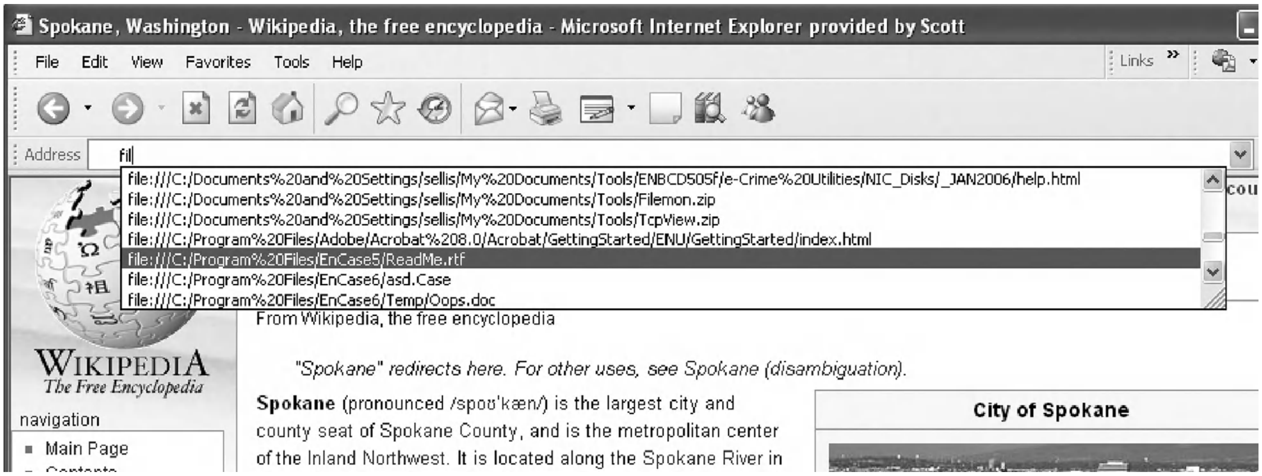

FIGURE 33.4 Spawning a list of URLs that were never typed (the Google one is deleted).

traffic. Every machine is assigned an IP address and a MAC address. It is like an IP address on layer 3, but the MAC address sits on Layer 2. It is quite like a phone number in that it is unique. Software that is used to examine network traffic is categorized as a *sniffer*. Tools such as Wireshark and Colasoft are two examples of sniffers. They can be used to view, analyze, and capture all the IP traffic that comes across a port.

Switches are not promiscuous, however. To view the traffic coming across a switch you can either put a hub in line with the traffic (between the target and the switch) and plug the sniffer into the hub with it, or ports can be spanned. Spanning, or mirroring, allows one port on a switch to copy and distribute network traffic in a way such that the sniffer can see everything. The argument could be made in court that the wrong port was accidentally spanned, but this argument quickly falls apart because all network packets contain both the machine and IP address of a machine. ARP poisoning is the practice of spoofing another user's IP address, however. This would be the smartest defense, but if a hub is used on a switched port, with the hub wired directly to the port, a greater degree of forensic certainty can be achieved. The only two computers that should be connected to the hub are the examiner and target machines.

Protocols

In the world of IP, the various languages of network traffic that are used to perform various tasks and operations are called *protocols*. Each protocol has its own special way of organizing and forming its packets. Unauthorized protocols viewed on a port are a good example of a type of action that might be expected from a rogue machine or employee. Network sniffing for email (SMTP and POP) traffic and capturing it can, depending on the sniffer used, allow the examiner to view live email traffic coming off the target machine. Viewing the Web (HTTP) protocol allows the examiner to capture images and text from Web sites that the target is navigating, in real time.

Analysis

Once the capture of traffic has been completed, analysis must take place. Colasoft offers a packet analyzer that can carve out and filter out the various types of traffic. A good deal of traffic can be eliminated as just "noise" on the line. Filters can be created that will capture the specific protocols, such as VoIP. Examination of the protocols for protocol obfuscation can (if it is not found) eliminate the possibility that a user has a malware infection, and it can identify a user that is using open ports on the firewall to transmit illicit traffic. They sneak legitimate traffic over open ports, masking their nefarious activities over legitimate ports, knowing that the ports are open. This can be done with whitespace inside of an existing protocol, with HTTP, VoIP, and many others. The thing to look for, which will usually be clearly shown, is something like:

VOIP > SMTP

This basically means that VOIP is talking to a mail server. This is not normal.[3]

Another thing to look for is protocols coming off a box that isn't purposed for that task. It's all context: who should be doing what with whom. Why is the workstation suddenly popping a DNS server? A real-world example is when a van comes screaming into your neighborhood.

3. M. J. Staggs, FireEye, Network Analysis talk at CEIC 2008.

Two guys jump out and break down the door of your house and grab your wife and kids and drag them out of the house. Then they come and get you. Seems a little fishy, right? But it is a perfectly normal thing to have happen if the two guys are firemen, the van was a fire truck, and your house is on fire.

9. CYBER FORENSICS APPLIED

This section details the various ways in which cyber forensics is applied professionally. By no means does this cover the extent to which cyber forensics is becoming one of the hottest computer careers. It focuses on the consulting side of things, with less attention to corporate or law enforcement applications. Generally speaking, the average forensic consultant handles a broader variety of cases than corporate or law enforcement disciplines, with a broader applicability.

10. TRACKING, INVENTORY, LOCATION OF FILES, PAPERWORK, BACKUPS, AND SO ON

These items are all useful areas of knowledge in providing consultative advisement to corporate, legal, and law-enforcement clients. During the process of discovery and warrant creation, knowledge of how users store and access data at a very deep level is critical to success.

Testimonial

Even if the work does not involve the court system directly—for example, a technician that provides forensic backups of computers and is certified—you may someday be called to provide discovery in a litigation matter. Subsequently, you may be required to testify.

Experience Needed

In cyber forensics, the key to a successful technologist is experience. Nothing can substitute for experience, but a good system of learned knowledge that represents at least the last 10 years is welcome.

Job Description, Technologist

Practitioners must possess extreme abilities in adapting to new situations. The environment is always changing.

Job description:

Senior Forensic Examiner and eDiscovery Specialist Prepared by Scott R. Ellis, 11/01/2007.

- Forensics investigative work which includes imaging hard drives, extracting data and files for ediscovery production, development of custom scripts as required to extract or locate data. On occasion this includes performing detailed analyses of user activity, images, and language that may be of an undesirable, distasteful, and potentially criminal format. For this reason, a manager must be notified immediately upon the discovery of any such materials.
- Creation of detailed reports that lay out findings in a meaningful and understandable format. All reports will be reviewed and OK'd by manager before delivery to clients.
- Use of software tools such as FTK, EnCase, VMware, Recovery for Exchange, IDEA, LAW, and Relativity.
- Processing ediscovery and some paper discovery.
- Be responsive to opportunities for publication such as papers, articles, blog, or book chapter requests. All publications should be reviewed by manager and marketing before being submitted to requestor.
- Use technology such as servers, email, time reporting, and scheduling systems to perform job duties and archive work in client folders.
- Managing lab assets (installation of software, Windows updates, antivirus, maintaining backup strategy, hardware installation, tracking hardware and software inventory).
- Some marketing work
- Work week will be 40 hours per week, with occasional weekends as needed to meet customer deadlines.
- Deposition or testimony as needed.
- Occasional evenings and out of town to accommodate client schedules for forensic investigative work.
- Occasional evenings and out of town to attend seminars, CPE or technology classes as suggested by self or by manager, and marketing events.
- Other technology related duties as may be assigned by manager in the support of the company mission as it relates to technology or forensic technology matters.

Job Description Management

A manager in cyber forensics is usually a working manager. He is responsible for guiding and developing staff as well as communicating requirements to the executive level. His work duties will typically encompass everything mentioned in the previous description.

Commercial Uses

Archival, ghosting images, dd, recover lost partitions, etc. are all applications of cyber forensics at a commercial level. Data recovery embraces a great many of the practices

typically attributed to cyber forensics. Archival and retrieval of information for any number of purposes, not just litigation, is required as is a forensic level of system knowledge.

Solid Background

To become a professional practitioner of cyber forensics, there are three requirements to a successful career. Certainly there are people, such as many who attain certification through law-enforcement agencies, that have skipped or bypassed completely the professional experience or scientific training necessary to be a true cyber forensic scientist. That is not to degrade the law-enforcement forensic examiner. His mission is traditionally quite different from that of a civilian, and these pros are frighteningly adept and proficient at accomplishing their objective, which is to locate evidence of criminal conduct and prosecute in court. Their lack of education in the traditional sense should never lead one to a desultory conclusion. No amount of parchment will ever broaden a mind; the forensic examiner must have a broad mind that eschews constraints and boxed-in thinking.

The background needed for a successful career in cyber forensics is much like that of any other except that, as a testifying expert, publication will give greater credence to a testimony than even the most advanced pedigree. The exception would be the cyber forensic scientist who holds a Ph. D. and happened to write her doctoral thesis on just the thing that is being called into question on the case. Interestingly, at this time, this author has yet to meet anyone with a Ph. D. (or any university degree for that matter), in cyber forensics. We can then narrow down the requirements to these three items. Coincidentally, these are also the items required to qualify as an expert witness in most courts:

- Education
- Programming and Experience
- Publications

The weight of each of these items can vary. To what degree depends on who is asking, but suffice it to say that a deficiency in any area may be overcome by strengths in the other two. The following sections provide a more in-depth view of each requirement.

Education/Certification

A strong foundation at the university level in mathematics and science provides the best mental training that can be obtained in cyber forensics. Of course, anyone with an extremely strong understanding of computers can surpass and exceed any expectations in this area. Of special consideration are the following topics. The best forensic examiner has a strong foundation in these areas and can qualify not just as a forensic expert with limited ability to testify as to the functions and specific mechanical abilities of software, but as a cyber expert who can testify to the many aspects of both hardware and software.

Understand how database technologies, including MS SQL, Oracle, Access, My SQL, and others, interact with applications and how thin and fat clients interact and transfer data. Where do they store temporary files? What happens during a maintenance procedure? How are indexes built, and is the database software disk aware?

Programming and Experience

Background in cyber programming is an essential piece. The following software languages must be understood by any well-rounded forensic examiner:

- Java
- JavaScript
- ASP/.NET
- HTML
- XML
- Visual Basic
- SQL

Develop a familiarity with the purpose and operation of technologies that have not become mainstream but have a devoted cult following. At one time such things as virtualization, Linux, and even Windows lived on the bleeding edge, but from being very much on the "fringe" have steadily become more mainstream.

- If it runs on a computer and has an installed base of greater than 10,000 users, it is worth reviewing.
- Internet technologies should be well understood. JavaScript, Java, HTML, ASP, ASPRX, cold fusion, databases, etc. are all Internet technologies that may end up at the heart of a forensic examiner's investigation.
- Experience. Critical to either establishing oneself in a career as a corporate cyber forensic examiner or as a consultant, experience working in the field provides the confidence and knowledge-base needed to successfully complete a forensic examination. From cradle to grave, from the initial interviews with the client to forensic collection, examination, reporting, and testifying, experience will guide every step. No suitable substitute exists. Most forensic examiners come into the career later in life after serving as a network or software consultant. Some arrive in this field after years in law enforcement where almost anyone who can turn on a computer winds up taking some cyber forensic training.

Communications

- Cyber forensics is entirely about the ability to look at a cyber system and subsequently explain, in plain English, the analysis. A typical report may consist of the following sections:
  - Summary
  - Methodology
  - Narrative
  - Healthcare information data on system
  - User access to credit-card numbers
  - Date range of possible breach and order handlers
  - Distinct list of operators
  - Russell and Crist Handlers
  - All other users logged in during Crist/Russel Logins
- Login failures activity coinciding with account activity
- All Users:
  - User access levels possible ingress/egress
  - Audit trail
  - Login failures
  - Conclusion
  - Contacts/examiners

Each section either represents actual tables, images, and calculated findings, or it represents judgments, impressions, and interpretations of those findings. Finally, the report should contain references to contacts involved in the investigation. A good report conveys the big picture, and translates findings into substantial knowledge without leaving any trailing questions asked and unanswered. Sometimes findings are arrived at through a complex procedure such as a series of SQL queries. Conclusions that depend on such findings should be as detailed as necessary so that opposing experts can reconstruct the findings without difficulty.

Almost any large company requires some measure of forensic certified staff. Furthermore, the forensic collection and ediscovery field continues to grow. Virtually every branch of law enforcement—FBI, CIA, Homeland Security, and state and local agencies—all use cyber forensics to some degree. Accounting firms and law firms of almost any size greater than 20 need certified forensic and ediscovery specialists that can both support their forensic practice areas as well as grow business.

Publications

Publishing articles in well-known trade journals goes a long way toward establishing credibility. The following things are nearly always true:

- A long list of publications not only creates in a jury the perception that the expert possess special knowledge that warrants publication; it also shows the expert's ability to communicate. Articles published on the Internet typically do not count unless they are for well-known publications that have a printed publication as well as an online magazine.
- Publishing in and of itself creates a certain amount of risk. Anything that an expert writes or says or posts online may come back to haunt him in court. Be sure to remember to check, double check, and triple check anything that could be of questionable interpretation.
- When you write, you get smarter. Writing forces an author to conduct research and refreshes the memory on long unused skills.

Getting published in the first place is perhaps the most difficult task. Make contact with publishers and editors at trade shows. Ask around, and seek to make contact and establish relationships with published authors and bloggers. Most important, always seek to gain knowledge and deeper understanding of the work.

11. TESTIFYING AS AN EXPERT

Testifying in court is difficult work. As with any type of performance, the expert testifying must know her material, inside and out. She must be calm and collected and have confidence in her assertions. Often, degrees of uncertainty may exist within a testimony. It is the expert's duty to convey those "gray" areas with clarity and alacrity. She must be able to confidently speak of things in terms of degrees of certainty and clear probabilities, using language that is accessible and readily understood by the jury.

In terms of degrees of certainty, often we find ourselves discussing the "degree of difficulty" of performing an operation. This is usually when judges ask whether or not an operation has occurred through direct user interaction or through an automated, programmatic, or normal maintenance procedure. For example, it is well within the normal operation of complex database software to reindex or compact its tables and reorganize the way the data is arranged on the surface of the disk. It is not, however, within the normal operation of the database program to completely obliterate itself and all its program, help, and system files 13 times over a period of three weeks, all in the time leading up to requests for discovery from the opposition. Such information, when forensically available, will then be followed by the question of "Can we know *who* did it?" And that question, if the files exist on a server where security is relaxed, can be nearly impossible to answer.

Degrees of Certainty

Most cyber forensic practitioners ply their trade in civil court. A typical case may involve monetary damages or

loss. From a cyber forensics point of view, evidence that you have extracted from a computer may be used by the attorneys to establish liability, that the plaintiff was damaged by the actions of the defendant. Your work may be the lynchpin of the entire case. You cannot be wrong. The burden to prove the amount of damages is less stringent once you've established that damage was inflicted, and since a single email may be the foundation for that proof, its provenance should prevail under even the most expert scrutiny. Whether or not the damage was inflicted may become a point of contention that the defense uses to pry and crack open your testimony.

The following sections may prove useful in your answers. The burden of proof will fall on the defense to show that the alleged damages are not accurate. There are three general categories of "truth" that can be used to clarify for a judge, jury, or attorney the weight of evidence. See the section on "Rules of Evidence" for more on things such as relevance and materiality.

Generally True

Generally speaking, something is generally true if under normal and general use the same thing always occurs. For example, if a user deletes a file, generally speaking it will go into the recycle bin. This is not true if:

- The user holds down a Shift key when deleting
- The recycle bin option "Do not move files to the recycle bin. Remove files immediately when deleted," is selected
- An item is deleted from a server share or from another computer that is accessing a local user share

Reasonable Degree of Certainty

If it smells like a fish and looks like a fish, generally speaking, it is a fish. However, without dissection and DNA analysis, there is the possibility that it is a fake, especially if someone is jumping up and down and screaming that it is a fake. Short of expensive testing, one may consider other factors. Where was the fish found? Who was in possession of the fish when it was found? We begin to rely on more than just looking at the fish to see if it is a fish.

Cyber forensic evidence is much the same (see checklist: "An Agenda For Action For Retrieval And Identification Of Evidence"). For example, in an employment dispute, an employee may be accused of sending sensitive and proprietary documents to her personal Webmail account. The employer introduces forensic evidence that the files were sent from her work email account during her period of employment on days when she was in the office.

Pretty straightforward, right? Not really. Let's go back in time to two months before the employee was fired. Let's go back to the day after she got a very bad performance review and left for the day because she was so upset. Everyone knew what was going on, and they knew that her time is limited. Two weeks later she filed an EEOC complaint. The IT manager in this organization, a seemingly mild-mannered, helpful savant, was getting

An Agenda for Action for Retrieval and Identification of Evidence

The computer forensics specialist should ensure that the following provisional list of actions for retrieval and identification of evidence are adhered to (Check All Tasks Completed):

_____**1.** Protect the subject computer system during the forensic examination from any possible alteration, damage, data corruption, or virus introduction.

_____**2.** Discover all files on the subject system. This includes existing normal files, deleted yet remaining files, hidden files, password-protected files, and encrypted files.

_____**3.** Recover all (or as much as possible) of discovered deleted files.

_____**4.** Reveal (to the greatest extent possible) the contents of hidden files as well as temporary or swap files used by both the application programs and the operating system.

_____**5.** Access (if possible and legally appropriate) the contents of protected or encrypted files.

_____**6.** Analyze all possibly relevant data found in special (and typically inaccessible) areas of a disk. This includes but is not limited to what is called unallocated space on a disk (currently unused, but possibly the repository of previous data that is relevant evidence), as well as slack space in a file (the remnant area at the end of a file in the last assigned disk cluster, that is unused by current file data, but once again, may be a possible site for previously created and relevant evidence).

_____**7.** Print out an overall analysis of the subject computer system, as well as a listing of all possibly relevant files and discovered file data.

_____**8.** Provide an opinion of the system layout; the file structures discovered; any discovered data and authorship information; any attempts to hide, delete, protect, and encrypt information; and anything else that has been discovered and appears to be relevant to the overall computer system examination.

_____**9.** Provide expert consultation and/or testimony, as required.

ready to start his own company as a silent partner in competition with his employer. He wanted information. His partners want information in exchange for a 20% stake. As an IT manager, he had administrative rights and could access the troubled employee's email account and began to send files to her Webmail account. As an IT administrator, he had system and network access that would easily allow him to crack her Webmail account and determine the password. All he had to do was spoof her login page and store it on a site where he could pick it up from somewhere else. If he was particularly interested in keeping his own home and work systems free of the files, he could wardrive her house, hack her home wireless (lucky him, it is unsecured), and then use terminal services to access her home cyber, log into her Webmail account (while she is home), and view the files to ensure that they appear as "read." This scenario may seem far-fetched but it is not; this is not hard to do.

For anyone with the IT manager's level of knowledge, lack of ethics, and opportunity, this is likely the *only* way that he would go about stealing information. There is no other way that leaves him so completely out of the possible running of suspects.

There is no magic wand in cyber forensics. The data is either there or it isn't, despite what Hollywood says about the subject. If an IT director makes the brash decision to reinstall the OS on a system that has been compromised and later realizes he might want to use a forensic investigator to find out what files were viewed, stolen, or modified, he can't just dial up his local forensics tech and have him pop in over tea, wave his magic wand, and recover all the data that was overwritten. Here is the raw, unadulterated truth: If you have 30 GB of unallocated clusters and you copy the DVD *Finding Nemo* onto the drive until the disk is full, nobody (and I really mean this), *nobody* will be able to extract a complete file from the unallocated clusters. Sure, they might find a couple of keyword hits in file slack and maybe, just maybe, if the stars align and Jupiter is in retrograde and Venus is rising, maybe they can pull a tiny little complete file out of the slack or out of the MFT. Small files, less than 128 bytes, are stored directly in the MFT and won't ever make it out to allocated space. This can be observed by viewing the $MFT file.

When making the determination "reasonable degree of forensic certainty," *all* things must be considered. Every possible scenario that could occur must flash before the forensic practitioner's eyes until only the most reasonable answer exists, an answer that is supported by all the evidence, not just part of it. This is called *interpretation*, and it is a weigh of whether or not a preponderance of evidence actually exists. The forensic expert's job is not to decide whether a preponderance of evidence exists. His job is to fairly, and truthfully, present the facts and his interpretation of the individual facts. Questions an attorney might ask a cyber forensics practitioner on the stand:

- Did the user delete the file?
- Could someone else have done it?
- Could an outside process have downloaded the file to the computer?
- Do you know for certain how this happened?
- Did you see Mr. Smith delete the files?
- How do you know he did?
- Isn't it true, Mr. Expert, that you are being paid to be here today?

These are not "Yes or no" questions. Here might be the answers:

- I'm reasonably certain he did.
- Due to the security of this machine, it's very unlikely that someone else did it.
- There is evidence to strongly indicate that the photos were loaded to the computer from a digital camera, not the Internet.
- I am certain, without doubt, that the camera in Exhibit 7a is the same camera that was used to take these photos and that these photos were loaded to the computer while username CSMITH was logged in.
- I have viewed forensic evidence that strongly suggests that someone with Mr. Smith's level of access and permissions to this system did, in fact, delete these files on 12/12/2009.
- I'm not sure I didn't just answer that.
- I am an employee of The Company. I am receiving my regular compensation and today is a normal workday for me.

Be careful, though. Reticence to answer in a yes-or no fashion may be interpreted by the jury as uncertainty. If certainty exists, say so. But it is always better to be honest and admit uncertainty than to attempt to inflate one's own ego by expressing certainty where none exists. Never worry about the outcome of the case. You can't care about the outcome of the trial. Guilt or innocence cannot be a factor in your opinion. You must focus on simply answering the questions in front of you that demand to be answered.

Certainty without Doubt

Some things on a computer can happen only in one fashion. For example, if a deleted item is found in the recycle bin, there are steps that must be taken to ensure that "it is what it is":

- Was the user logged in at the time of deletion?
- Are there link files that support the use or viewing of the file?

TABLE 33.4 Example of a Forensic View of Files Showing Some Alteration or Masking of Dates.

Filename	Date Created	File Properties	Original Path
Kitty.jpg	5/12/2007	File, Archive	
summaryReport.doc	7/12/2007	File, Deleted, Overwritten	Kitty.jpg
Marketing_flyer.pdf	2/12/2008	File, Deleted, Overwritten	Kitty.jpg

- Was the user with access to the user account at work that day?
- What are the permissions on the folder?
- Is the deleted file in question a system file or a user-created file located in the user folders?
- Is the systems administrator beyond reproach or outside the family of suspects?

If all of these conditions are met, you may have arrived at certainty without doubt. Short of reliable witnesses paired with physical evidence, it is possible that there will always be other explanations, that uncertainty to some degree can exist. It is the burden of the defense and the plaintiff to understand and resolve these issues and determine if, for example, hacker activity is a plausible defense. I have added the stipulation of reliable witnesses because, in the hands of a morally corrupt forensic expert with access to the drive and a hex editor, a computer can be undetectably altered. Files can be copied onto a hard drive in a sterile manner that, to most trained forensic examiners, could appear to be original. Even advanced users are capable of framing the evidence in such a way as to render the appearance of best evidence, but a forensic examination may lift the veil of uncertainty and show that data has been altered, or that something *isn't quite right*. For example, there are certain conditions that can be examined that can show with certainty that the time stamps on a file have been somehow manipulated or are simply incorrect, and it is likely that the average person seeking to plant evidence will not know these tricks (see Table 33.4). The dates on files that were overwritten may show that "old" files overwrote newer files. This is impossible.

As shown here, the file kitty.jpg overwrites files that appear to have been created on the system after it. Such an event may occur when items are copied from a CDROM or unzipped from a zip file.

12. BEGINNING TO END IN COURT

In most courts in the world, the accuser goes first and then the defense presents its case. This is for the very logical reason that if the defense goes first, nobody would know what they are talking about. The Boulder Bar has a Bar manual located at www.boulder-bar.org[4] that provides a more in-depth review of the trial process than can be presented here. Most states and federal rules are quite similar, but nothing here should be taken as legal advice; review the rules for yourself for the courts where you will be testifying. The knowledge isn't necessary, but the less that you seem to be a fish out of water, the better. This section *does not* replace true legal advice, it is strictly intended for the purpose of education. The manual located at the Boulder Bar Web site was created for a similar reason that is clearly explained on the site. The manual there was specifically developed without any "legalese," which makes it very easy to understand.

Defendants, Plaintiffs, and Prosecutors

When someone, an individual or an organization, decides it has a claim of money or damages against another individual or entity, they file a claim in court. The group filing the claim is the plaintiff, the other parties are the defendants. Experts may find themselves working for strictly defendants, strictly plaintiffs, or a little bit of both. In criminal court, charges are "brought" by an indictment, complaint, information, or a summons and complaint.

Pretrial Motions

Prior to the actual trial, there may be many, many pretrial motions and hearings. When a motion is filed, such as when the defense in a criminal case is trying to prevent certain evidence from being seen or heard by the jury, a hearing is called and the judge decides whether the motion has any merit. In civil court, it may be a hearing to decide whether the defense has been deleting, withholding, or committing other acts of discovery abuse. Cyber forensic practitioners will find that they may be called to testify at any number of hearings prior to the trial, and then they may not be needed at the trial at all,

4. Boulder Bar, www.boulder-bar.org/bar_media/index.html.

or the defense and plaintiff may reach a settlement and there will be no trial at all.

Trial: Direct and Cross-Examination

Assuming that there is no settlement or plea agreement, a case will go to trial. The judge will first ask the prosecutor or plaintiff whether they want to make an opening statement. Then the defense will be asked. Witnesses will be called, and if it is the first time appearing in the particular trial as an expert, the witness will be qualified, as discussed in a moment. The party putting on the witness will conduct a direct examination and the other side will very likely cross-examine the witness afterward. Frequently the two sides will have reviewed the expert report and will ask many questions relating directly to it. "Tricks" may be pulled by either attorney at this point. Certain prosecutors have styles and techniques that are used in an attempt to either rattle the expert's cage or simply intimidate him into a state of nervousness so that he will appear uncertain and unprepared. These prosecutors are not interested in justice. They are interested in winning because their career rotates around their record of wins/losses.

Rebuttal

After a witness has testified and undergone direct examination and cross-examination, the other side may decide to bring in an expert to discuss or refute. The defendant may then respond to the prosecution's witness in *rebuttal*. In criminal court, when the state or the government (sometimes affectionately referred to by defense attorneys as "The G") brings a case against an individual or organization, the attorneys that prosecute the case are called the state's attorney, district attorney, assistant U.S. attorney (AUSA), or simply prosecutor.

Surrebuttal

This is the plaintiff (or prosecutor's!) response to rebuttal. Typically the topics of surrebuttal will be limited to those topics that are broached in rebuttal, but the rules for this are probably best left to attorneys to decipher; this author has occasionally been asked questions that should have been deemed outside the bounds of the rebuttal. This could most likely be attributed to a lack of technical knowledge on the part of the attorneys involved in the case.

Testifying: Rule 702. Testimony by Experts

Rule 702 is a federal rule of civil procedure that governs expert testimony. The judge is considered the "gatekeeper," and she alone makes the decision as to whether or not the following rule is satisfied:

If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise, if (1) the testimony is based upon sufficient facts or data, (2) the testimony is the product of reliable principles and methods, and (3) the witness has applied the principles and methods reliably to the facts of the case (U.S. Courts, Federal Rules of Evidence, Rule 702).

There are certain rules for qualifying as an expert. In court, when an expert is presented, both attorneys may question the expert on matters of background and expertise. This process is referred to as *qualification* and, if an "expert" does not meet the legal definition of expert, he may not be allowed to testify. This is a short bullet list of items that will be asked in qualifying as an expert witness:

- How long have you worked in the field?
- What certifications do you hold in this field?
- Where did you go to college?
- Did you graduate? What degrees do you have?
- What are your publications?

You may also be asked if you have testified in other proceedings. It is important to always be honest when on the stand. Perjury is a very serious crime and can result in jail time. All forensics experts should familiarize themselves with Federal Rules 701−706 as well as understand the purpose, intent, and results of a successful *Daubert* challenge, wherein an expert's opinion or the expert himself may be challenged and, if certain criteria are met, may have his testimony thrown out. It is accepted and understood that experts may have reasonably different conclusions given the same evidence.

When testifying, stay calm (easier said than done). If you've never done it, approaching the bench and taking the witness stand may seem like a lot of fun. In a case where a lot is on the line and it all depends on the expert's testimony, nerves will shake and cages will be rattled. The best advice is to stay calm. Drink a lot of water. Drinking copious amounts of water will, according to ex-Navy Seal Mike Lukas, dilute the affect of adrenalin in the bloodstream.

Testifying in a stately and austere court of law may seem like it is the domain of professors and other ivory tower enthusiasts. However, it is something that pretty much anyone can do that has a valuable skill to offer, regardless of educational background. Hollywood often paints a picture of the expert witness as a consummate professorial archetype bent on delivering "just the facts." It is true that expert witnesses demand top dollar in the

consulting world. Much of this is for the reason that a great deal is at stake once the expert takes the stand. There is also a very high inconvenience factor. When on the stand for days at a time, one can't simply take phone calls, respond to emails, or perform other work for other clients. There is a certain amount of business interruption that the fees must make up for somehow.

Testifying is interesting. Distilling weeks of intense, technical investigation into a few statements that can be understood by everyone in the courtroom is no small task. It is a bit nerve wracking, and one can expect to have high blood pressure and overactive adrenalin glands for the day. Drinking lots of water will ease the nerves better than anything (nonpharmaceutical). It can have other side effects, however, but it is better to be calm and ask the judge for a short recess as needed than to have shaky hands and a trembling voice from nerves. Caffeine is a bad idea.

Correcting Mistakes: Putting Your Head in the Sand

The interplay of examiner and expert in the case of cyber forensics can be difficult. Often the forensic examiner can lapse into speech and explanations that are so commonplace to her that she doesn't realize she is speaking fluent geek-speak. The ability to understand how she sounds to someone who doesn't understand technology must be cultivated. Practice by explaining to any six-year-old what it is you do.

Direct Testimony

Under direct questioning, your attorney will ask questions to which you will know the answer. A good expert will, in fact, have prepared a list of questions and reviewed the answers with the attorney and explained the context and justification for each question thoroughly. If it is a defense job, you will likely go first and testify as to what your investigation has revealed. Avoid using big words and do make some eye contact with the jury if you feel you need to explain something to them, but generally speaking, you should follow the attorney's lead. If she wants you to clarify something for the jury, you should do so, and at that time you should look at the jury. Generally, the rule of thumb is to look at the attorney who asked you the question. If the judge says, "Please explain to the jury . . ." then by all means, look at the jury.

Cross-Examination

The purpose of a cross-examination is to get the testifying expert to make a mistake or to discredit him. Sometimes (rarely) it is actually used to further understand and clarify things that were discussed in direct. In most cases, the attorney will do this by asking you questions about your experience or about the testimony the expert gave under direct. But there is another tactic that attorneys use. They ask a question that is completely unrelated to the topic you talked about. They know that the vast majority of time you spend is on the issues in your direct. For example, you may give a testimony about Last Accessed time stamps. Your entire testimony may be about Last Accessed time stamps. It may be the only issue in the case you are aware of. Then, on cross, the attorney asks a question about the behavior of the mail icon that appears on each line next to the subject line in an email. "Great," the expert thinks. "They recognize my expertise and are asking questions."

Stop. They are about to ask you an arcane question about a behavior in a piece of software in the hopes that you are overconfident and will answer from the hip and get the answer wrong. Because if you get this wrong, then everything else you said must be wrong, too. *Whenever* you are asked a question that does not relate to your previous testimony, pause. Pause for a long time. Give your attorney time to object. He might not know that he should object, but the fact is that you might get the answer wrong and even if there is no doubt in your mind that you know the answer, you should respond that you had not prepared to answer that question and would like to know more details. For example, what is the version of the software? What is the operating system? What service pack? If it is Office, what Office service pack? You need to make it clear that you need more information before you answer the question because, frankly, if the opposition goes down this road, they will try to turn *whatever* you say into the wrong answer.

As a forensic examiner, you may find yourself thinking that the reason they are asking these questions in such a friendly manner is because they forgot to ask their own expert and are trying to take advantage of your time because possibly this came up in a later conversation. This could very well be the case. Maybe the counselor is not trying to trip up the expert. Maybe the Brooklyn Bridge *can* be purchased for a dollar, too.

What is the best response to a question like this? If you give it a 10 count and your attorney hasn't objected, and the asking attorney has not abandoned the question, you may have to answer. There are many schools of thought on this. It is best to understand that a number of responses can facilitate an answer to difficult questions. One such response might be, "That is not really a forensics question" (if it's not), or "I'm not sure how that question relates back to the testimony I just gave." Or, if it is a software question, you can say, "Different software behaves differently, and I don't think I can answer that

question without more details. I don't typically memorize the behavior of every piece of software, and I'm afraid that if I answer from memory I may not be certain." At the end of the day, the expert should only speak to what he knows *with certainty*. There is very little room for error. Attorneys can back-pedal a certain amount to "fix" a mistake, but a serious mistake can follow you for a very long time and can hamper future testimony. For example, if you make statements about time stamps in one trial, and then in the next trial you make statements that interpret them differently, there is a good chance that the opposition will use this against you.

Fortunately, when cyber forensic experts testify in a defense trial, the testimony can last a number of hours. Great care is usually taken by the judge to ensure that understanding of all the evidence is achieved. This can create a very long transcript that is difficult to read, understand, and recall with accuracy. For this reason, rarely will bits and pieces of testimony be used against a testifying expert in a future trial. This is not, of course, to say that it can't or won't happen.

It is important, in terms of both setting expectations and understanding legal strategy, for an expert witness to possess passable knowledge of the trial process. Strong familiarity with the trial process can benefit both the expert and the attorneys as well as the judge and the court reporter.

13. SUMMARY

Computers have appeared in the course of litigation for over 36 years. In 1977, there were 291 U.S. federal cases and 246 state cases in which the word *computer* appeared and which were sufficiently important to be noted in the Lexis database. In 2012, according to industry analysts, those figures in the U.S. have risen dramatically, to 3,250,514 U.S. federal cases and 2,750,177 state cases in which the word *cyber* appeared. In the UK, there were only 20 in 1977, with a rise to 220,372 in 2012. However, as early as 1968, the computer's existence was considered sufficiently important for special provisions to be made in the English Civil Evidence Act.

The following description is designed to summarize the issues rather than attempt to give a complete guide. As far as one can tell, noncontentious cases tend not to be reported, and the arrival of computers in commercial disputes and in criminal cases did not create immediate difficulties. Judges sought to allow cyber-based evidence on the basis that it was no different from forms of evidence with which they were already familiar: documents, business books, weighing machines, calculating machines, films, and audio tapes. This is not to say that such cases were without difficulty; however, no completely new principles were required. Quite soon, though, it became apparent that many new situations were arising and that analogies with more traditional evidential material were beginning to break down. Some of these were tackled in legislation, as with the English 1968 Act and the U.S. Federal Rules of Evidence in 1976. But many were addressed in a series of court cases. Not all of the key cases deal directly with computers. But they do have a bearing on them as they relate to matters that are characteristic of cyber-originated evidence. For example, cyber-originated evidence or information that is not immediately readable by a human being is usually gathered by a mechanical counting or weighing instrument. The calculation could also be performed by a mechanical or electronic device.

The focus of most of this legislation and judicial activity was determining the admissibility of the evidence. The common law and legislative rules are those that have arisen as a result of judicial decisions and specific law. They extend beyond mere guidance. They are rules that a court must follow; the thought behind these rules may have been to impose standards and uniformity in helping a court test authenticity, reliability, and completeness. Nevertheless, they have acquired a status of their own and in some cases prevent a court from making ad hoc common sense decisions about the quality of evidence. The usual effect is that once a judge has declared evidence inadmissible (that is, failing to conform to the rules), it is never put to a jury; for a variety of reasons that will become apparent shortly. It is not wholly possible for someone interested in the practical aspects of computer forensics (that is, the issues of demonstrating authenticity, reliability, completeness, or lack thereof) to separate out the legal tests.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Cyber forensics is the acquisition, preservation, and analysis of electronically stored information (ESI) in such a way that ensures its admissibility for use as either evidence, exhibits, or demonstratives in a court of law.
2. True or False? EnCase is a commonly used forensic software program that does not allow a cyber forensic technologist to conduct an investigation of a forensic hard disk copy.
3. True or False? On a server purposed with storing surveillance video, there are three physical hard drives.

4. True or False? Cyber forensics is one of the many cyber-related fields in which the practitioner will be found in the courtroom on a given number of days of the year.
5. True or False? A temporary restraining order (TRO) will often be issued in intellectual property or employment contract disputes.

Multiple Choice

1. Typically the forensic work done in a ______________ will involve collecting information about one of the parties to be used to show that trust has been violated.
   - **A.** Security incident
   - **B.** Security breach
   - **C.** Computer virus
   - **D.** Divorce case
   - **E.** Security policy
2. When one company begins selling a part that is _______ by another company, a lawsuit will likely be filed in federal court.
   - **A.** Assigned
   - **B.** Breached
   - **C.** Detected
   - **D.** Patented
   - **E.** Measured
3. When a forensics practitioner needs to capture the data on a hard disk, he/she does so in a way that is:
   - **A.** Forensically acquired
   - **B.** Forensically mirrored
   - **C.** Forensically sound
   - **D.** Forensically imaged
   - **E.** Forensically booted
4. Before conducting any sort of a capture, all steps should be documented and reviewed with a ______ before proceeding
   - **A.** Observer
   - **B.** Investigator
   - **C.** Counsel
   - **D.** Forensic Expert
   - **E.** Judge
5. FAT12, FAT16, and FAT32 are all types of file systems?
   - **A.** FAT12
   - **B.** FAT16
   - **C.** FAT32
   - **D.** FAT64
   - **E.** All of the above

Optional Team Case Project

Problem

What can an organization do to protect their data and minimize their chances of losing data?

Chapter 34

Cyber Forensics and Incident Response

Cem Gurkok
Verizon Terremark

1. INTRODUCTION TO CYBER FORENSICS

Cyber forensics and incident response go hand in hand. Cyber forensics reduces the occurrence of security incidents by analyzing the incident to understand, mitigate, and provide feedback to the actors involved. To perform incident response and related activities, organizations should establish an incident plan, a computer security incident response team (CSIRT), or a computer emergency response team (CERT) to execute the plan and associated protocols.

Responding to Incidents

In an organization, there is a daily occurrence of events within the IT infrastructure, but not all of these events qualify as incidents. It is important for the incident response team to be able to distinguish the difference between events and incidents. Generally, incidents are events that violate an organization's security policies, end-user agreements, or terms of use. SANS (sans.org) defines an incident as an adverse event in an information system or network, or the threat of an occurrence of such an event. Denial-of-service attacks, unauthorized probing, unauthorized entry, destruction or theft of data, and changes to firmware or operating systems can be considered incidents.

Generally, incident response handling comprises incident reporting, incident analysis, and incident response. Incident reporting takes place when a report or indications of an event are sent to the incident response team. The team then performs an incident analysis by examining the report, available information, and evidence or artifacts related to the event to qualify the event as an incident, correlate the data, and assess the extent of damage, source, and plan potential solutions. Once the analysis is over, then the team responds to mitigate the incident by containing and eradicating the incident. This is followed by the creation of a detailed report about the incident.

Applying Forensic Analysis Skills

Forensic analysis is usually applied to determine who, what, when, where, how, and why an incident took place. The analysis may include investigating crimes and inappropriate behavior, reconstructing computer security incidents, troubleshooting operational problems, supporting due diligence for audit record maintenance, and recovering from accidental system damage. The incident response team should be trained and prepared to be able to collect and analyze the related evidence to answer these questions. Data collection is a very important aspect of incident response since evidence needs to be collected in a forensically sound manner to protect its integrity and confidentiality. The incident responder needs to have the necessary skills and experience to be able to meet the collection requirements.

Forensic analysis is the process whereby the collected data is reviewed and scrutinized for the lowest level of evidence (deleted data in slack space) it can offer. The analysis may involve extracting email attachments, building timelines based on file times, reviewing browser history and in-memory artifacts, decrypting encrypted data, and malware reverse engineering. Once the analysis is complete, the incident responder will produce a report describing all the steps taken starting from the initial incident report till the end of the analysis. One of the most important skills a forensic analyst can have is note taking and logging, which becomes very important during the reporting phase and, if it ever comes to it, in court. These considerations related to forensics should be addressed in organizational policies. The forensic policy should clearly define the responsibilities and roles of the actors involved. The policies should also address the types of activities that should be undertaken under certain circumstances and the handling of sensitive information.

Distinguishing between Unpermitted Corporate and Criminal Activity

We previously defined incidents as events that are not permitted by a certain organization's policies. The

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00034-9

incident response team should also be aware of several federal laws that can help them to identify criminal activity to ensure that the team does not commit a crime while responding to the incident. Some of these federal laws are:

- The Foreign Intelligence Surveillance Act of 1978
- The Privacy Protection Act of 1980
- The Computer Fraud and Abuse Act of 1984
- The Electronic Communications Privacy Act of 1986
- The Health Insurance Portability and Accountability Act of 1996 (HIPAA)
- The Identity Theft and Assumption Deterrence Act of 1998
- The USA Patriot Act of 2001

When an incident response team comes across incidents relevant to these laws, they should consult with their legal team. They should also contact appropriate law enforcement agencies.

2. HANDLING PRELIMINARY INVESTIGATIONS

An organization should be prepared beforehand to properly respond to incidents and mitigate them in the shortest time possible. An incident response plan should be developed by the organization and tested on a regular basis. The plan should be written in an easily understood and implemented fashion. The incident response team and related staff should also be trained on an ongoing basis to keep them up to date with the incident response plan, latest threats, and defense techniques.

Planning for Incident Response

Organizations should be prepared for incidents by identifying corporate risks, preparing hosts and network for containment and eradication of threats, establishing policies and procedures that facilitate the accomplishment of incident response goals, creating an incident response team, and preparing an incident response toolkit to be used by the incident response team.

Communicating with Site Personnel

All departments and staff that have a part in an incident response should be aware of the incident response plan and should be regularly trained as to its content and implementation. The plan should include the mode of communication with the site personnel. The site personnel should clearly log all activity and communication, including the date and time in a central repository that is backed up regularly. This information should be reviewed by all of the incident response team members to assure all players are on the same page. Continuity and the distribution of information within the team is critical in the swift mitigation of an incident. An incident response team leader should be assigned to an incident and should make sure all team members are well informed and acting in a coordinated fashion.

Knowing Your Organization's Policies

An organization's policies will have an impact on how incidents are handled. These policies are usually very comprehensive and effective computer forensics policies that include considerations, such as contacting law enforcement, performing monitoring, and conducting regular reviews of forensic policies, guidelines, and procedures. Banks, insurance companies, law firms, governments, and health care institutions have such policies. Generally, policies should allow the incident response team to monitor systems and networks and perform investigations for reasons described in the policies. Policies may be updated frequently to keep up with the changes to laws and regulations, court rulings, and jurisdictions.

Forensics policies define the roles and responsibilities of the staff involved, including users, incident handlers, and IT staff. The policy indicates when to contact internal teams or reach out to external organizations. It should also discuss how to handle issues arising from jurisdictional conflicts. Policies also discuss the valid use of anti-forensics tools and techniques (sanitation and privacy versus malicious use, such as hiding evidence). How to maintain the confidentiality of data and the retention time of the data is also governed by organizational policies.

Minimizing the Impact on Your Organization

The goals of incident response include minimizing disruption to the computer and network operations, and limiting the exposure and compromise of sensitive data. To be able to meet these goals, incident response preparedness, planning, and proper execution following related policies are crucial. Incident response teams should minimize the downtimes of business critical systems once the evidence has been gathered and the systems have been cleared of the effects of the incident. Incident response teams should also identify an organization's risks and work with appropriate teams to continuously test and eliminate any vulnerability. Red team/blue team-type exercises whereby one team plays the role of malicious people and the other team the role of incident responders can provide good training for the staff and expose previously unknown risks and vulnerabilities. To minimize the impact of incidents, organizations should also establish and enforce security policies and procedures, gain management support for

security policies and incident response, keep systems updated and patched, train IT staff and end users, implement a strong credential policy, monitor network traffic and system logs, and implement and routinely test a backup policy.

Identifying the Incident Life Cycle

SANS (sans.org) defines the phases of the incident life cycle (see Figure 34.1).

Preparation

It's a matter of when rather than if an incident will happen. Therefore, it has become a top priority for an organization to be prepared for an incident. To be prepared, an organization must establish security plans and controls, make sure these plans and controls are continuously reviewed and updated to keep up with the evolving threats, and see that they are enforced in case of an incident. Organizations should be prepared to act swiftly to minimize the impact of any incident to maintain business continuity. Incident response teams should continuously train; test, and update the incident response plan to keep their skills honed.

Detection, Collection, and Analysis

The detection of an incident involves the observance and reporting of irregularities or suspicious activities to security or IT department staff members. Once an event has been reported and escalated to the incident response team, the event is evaluated to determine whether it warrants classification as an incident. If the event has been classified as an incident, the incident response team should move in to perform data collection on the affected systems that will later be used for analysis. During collection, it is important to work in accordance with the organization's policies and procedures and preserve a valid chain-of-custody. The person involved in collecting the data should make sure that the integrity of the data is maintained on both the original and working copies of the evidence. Once the relevant information has been captured, the incident response team should analyze the data to determine who, what, when, where, how, and why an incident took place.

FIGURE 34.1 Incident response life cycle.

Containment, Eradication, and Recovery

Once the involved systems and offending vectors have been analyzed, the incident response team should move in to contain the problem and eradicate it. It is crucial to contain an incident as fast as possible to minimize its impact on the business. This action can be as easy as disconnecting the system from the network or as hard as isolating a whole server farm from the production environment. Containment and eradication should strive to protect service integrity, sensitive data, hardware, and software. The recovery phase depends on the extent of the incidence. For example, it is easier to recover from an intrusion that was detected while it was affecting a single user than from an intrusion in which the lateral movement of the intruder is extensive. Most of the time, recovery involves backing up the unaffected data to use on the new systems. Operating systems and applications are usually installed fresh to avoid any type of contamination.

Post-Incident Activity

The post-incident phase involves documenting, reporting, and reviewing the incident. Documentation actually starts as soon as an event has been classified as an incident. The report should include all of the documentation compiled during the incident, the analysis methods and techniques, and all other findings. The person writing the report should keep in mind that the report might someday be used by law enforcement or in court. Finally, the incident response team should go over the report with the IT department and other involved parties to discuss how to improve the infrastructure to prevent similar incidents.

Capturing Volatile Information

Computer systems contain volatile data that is temporarily available either until a process exits or a system is shut down. Therefore, it is important to capture this data before making any physical or logical changes to the system to avoid tampering with evidence. Many incident responders have unwittingly destroyed memory-only resident artifacts by shutting down a system in the name of containment.

Volatile data is available as system memory (including slack and free space), network configuration, network connections and sockets, running processes, open files, login sessions, and operating system time. System memory can be captured by using sampling tools (MoonSols Windows Memory Toolkit, GMG Systems' KnTDD) as a

file and analyzed with the Volatility Framework to obtain the volatile data previously mentioned. The volatile data can also be captured individually with tools that are specific for each data type. The Microsoft Windows Sysinternals suite provides an extensive set of tools that can capture volatile data, such as login sessions, registry, process information, service information, shares, and loaded DLLs.

3. CONTROLLING AN INVESTIGATION

To control an investigation, the incident response team should have a forensics investigation plan, a forensics toolkit, and documented methods to secure the affected environment. An investigator should always keep in mind that the evidence collected and the analysis performed might be presented in court or used by law enforcement. Related documentation should be detailed and contain dates and times for each activity performed. To avoid challenges to the authenticity of evidence, investigators should be able to secure the suspect infrastructure, log all activity, and maintain a chain of custody.

Collecting Digital Evidence

It is important to an investigator to preserve data related to an incident as soon as possible to avoid the rapid degradation or loss of data in digital environments. Once the affected systems have been determined, volatile data should be captured immediately, followed by nonvolatile data, such as system users and groups, configuration files, password files and caches, scheduled jobs, system logs, application logs, command history, recently accessed files, executable files, data files, swap files, dump files, security software logs, hibernation files, temporary files, and complete file listings with times.

Chain of Custody and Process Integrity

The incident response team should be committed to collect and preserve evidence using methods that can support future legal or organizational proceedings. A clearly defined chain of custody is necessary to avoid allegations of tampering evidence. To accomplish this task, the team should keep a log of every entity who had physical custody of the evidence, document all of the actions performed on the evidence with the related date and time, make a working copy of the evidence for analysis, verify the integrity of the original and working copy, and store the evidence in secured location when not in use [1]. Also, before touching a physical system, the investigator should take a photograph of it. To ensure the integrity of the process, a detailed log should be kept of all the collection steps, and information about every tool used in the incident response process should be included.

Advantages of Having a Forensic Analysis Team

Forensic analysis is usually associated with crime investigations. Nowadays, due to the increase in computer-related malicious activity and growing digital infrastructure, forensic analysis is involved in incident response, operational troubleshooting, log monitoring, data recovery, data acquisition, audits, and regulatory compliance. Therefore, organizations can no longer rely on law enforcement due to resource and jurisdictional limitations. A violation of organizational policies and procedures might not concern law enforcement, leaving the organization to its own devices. It has become evident to organizations that maintaining capabilities to perform forensic analysis has become a business requirement to satisfy organizational and customer needs. While it may make sense for some organizations to maintain an internal team of forensic analysts, some might find it more beneficial to hire outside parties to carry out this function. Organizations should take cost, response time, and data sensitivity into consideration before making this decision [1]. Keeping an internal forensic analysis team might reduce cost depending on the scale of the incident, provide faster response due to familiarity with the infrastructure, and prevent sensitive data from being viewed by third parties.

Legal Aspects of Acquiring Evidence: Securing and Documenting the Scene

Securing the physical scene and documenting it should be one of the first steps an incident responder should take. This activity involves photographing the system setup, cabling, and general area, collecting and documenting all cables and attached devices, write-protecting all media, using anti-static packaging for transportation, maintaining proper temperature for stored devices, avoiding exposure to excessive electromagnetic fields, and logging all access to the area. The incident response team should keep an inventory of evidence handling supplies (chain of custody forms, notebooks, evidence storage bags, evidence tape), blank media, backup devices, and forensics workstations.

Processing and Logging Evidence

The goal of an investigation is to collect and preserve evidence that can be used for internal proceedings or courts of law. Investigators should be able to prove that the evidence has not been tampered with. To be able to get this evidence, the incident response team members should

receive training specifically addressing these issues and should practice these skills on an ongoing basis to stay sharp.

To properly process and log evidence, investigators should keep the evidence within a secured and controlled environment where all access is logged, and should document the collected evidence and its circulation among investigative entities. We cannot stress how important it is to associate each activity with a date and time.

4. CONDUCTING DISK-BASED ANALYSIS

To be able to process evidence in a manner that is admissible in a court of law, a lab and accompanying procedures should be established. This will ensure that the data integrity is not breached and that the data remains confidential—in other words, that the evidence remains forensically sound.

Forensics Lab Operations

To ensure forensic soundness, an investigator's process needs to be reliable, repeatable, and documented. To have a controlled and secure environment for the investigator to follow these steps, a forensic lab becomes a necessity.

The lab should be established in a physically secure building that is monitored 24/7; have a dedicated staff; have regularly upgraded and updated workstations dedicated to forensic analysis with related software installed; and have a disaster recovery plan in place.

Acquiring a Bit-Stream Image

Acquiring a bit-stream image involves producing a bit-by-bit copy of a hard drive on a separate storage device. By creating an exact copy of a hard drive, an investigator preserves all data on a disk, including currently unused and partially overwritten sectors. The imaging process should not alter the original hard drive to preserve the copy's admissibility as evidence. Selecting a proper imaging tool is crucial to produce a forensically sound copy. The National Institute of Standards and Technology (NIST) lists the requirements for a drive imaging tool as follows [1]:

- The tool shall make a bit-stream duplicate or an image of an original disk or a disk partition on fixed or removable media.
- The tool shall not alter the original disk.
- The tool shall be able to access both IDE and SCSI disks.
- The tool shall be able to verify the integrity of a disk image file.
- The tool shall log input/output (I/O) errors.
- The tool's documentation shall be correct.

The imaging of a hard drive can be performed using specialized hardware tools or by using a combination of computers and software.

Specialized Hardware

The Image MASSter Solo series hard drive duplicators generally support SATA, IDE, USB, eSATA, uSATA, SAS hard drives, and flash memory devices. They can hash the disk images, besides providing write-blocking, to ensure the integrity of the copies. The imaging process can be either disk-to-disk or disk-to-file.

The Digital Intelligence Forensic Duplicator units have the same properties as the Image MASSter Solo series. But they provide access to different hard drive formats through their protocol modules.

Software: Linux

The dd or dcfldd has been fully tested and vetted by NIST as a forensic imaging tool. It is a freeware utility for any Linux-based system and can copy every sector of hard drives. dcfldd is a dd-based software that enhances dd's output by providing status and time-to-completion output as the disk gets imaged and can split the output to smaller chunks. It can also hash the output to ensure data integrity. The following command as seen in Table 34.1 will read block sizes of 512 bytes, produce 2 GB chunks of a disk device defined as /dev/sdb, and calculate the MD5 hashes every 2 GB to ensure integrity. The hash values will be written to a file named md5.og. In the event of a read error, dcfldd will write zeroes in the copy.

Windows The AccessData FTK (Forensic Toolkit) Imager tool is a commercial disk-imaging tool distributed by AccessData. FTK supports storage of disk images in EnCase's file format, as well as in bit-by-bit (dd) format.

On the other hand, the Guidance EnCase tool is a commercial disk-imaging tool distributed by Guidance Software. Disk images are stored in the proprietary EnCase Evidence File Format, which contains compressed data prefixed with case metadata and contains hashes of the image data.

Enabling a Write Blocker

Write blockers are hardware- or software-based tools that allow the acquisition of hard drive images while

TABLE 34.1 Creating an Image of a Drive.

```
$ dcfldd if = /dev/sdb hash = md5 hashwindow = 2G
md5log = md5.log hashconv = after bs = 512 conv = noerror,
sync split = 2G splitformat = aa of = driveimage.dd
```

preventing any data from being written to the source hard drive. Therefore ensuring the integrity of the data involved. Write blockers can do this by only allowing read commands to pass through by blocking write commands or by letting only specific commands through. While copying data with a hardware write blocker, both the source and destination drives should be connected to the write blocking device, and in case of a software blocker, the blocking software should be activated first before copying [2]. After imaging is performed with a write blocker, calculating the hashes of both the source and destination images is essential to ensure data integrity. Some hardware write blockers that are used in the industry are as follows:

- Tableau Forensic Bridges
- WiebeTech WriteBlocker

Establishing a Baseline

It is important to maintain the integrity of the data being analyzed throughout the investigation. When dealing with disk drives, to maintain integrity, calculating the hashes of the analyzed images becomes crucial. Before copying or performing any analysis, the investigator should take a baseline hash of the original drives involved. The hash could be either just MD5 or a combination of MD5, SHA-1, and SHA-512. The baseline hash can be compared with hashes of any copies that are made thereafter for analysis or backup to ensure that the integrity of the evidence is maintained.

Physically Protecting the Media

After making copies of the original evidence hard drives, they should be stored in a physically secure location, such as a safe in a secured storage facility. These drives could be used as evidence in the event of prosecution. The chain of custody should also be maintained by labeling the evidence and keeping logs of date, time, and persons with whom the evidence has come into contact. During transportation, the hard drives should be placed in antistatic bags and should not be exposed to harsh environmental conditions. If possible, photographs of the evidence should be taken whenever they are processed, starting from the original location until the image acquisition stages.

Disk Structure and Recovery Techniques

Once a forensically sound copy of the evidence has been made, we can proceed to analyze its contents. There are different kinds of storage media: hard disk drives (HDD), solid state drives (SSD), digital video disks (DVD), compact disks (CD), flash memory, and other kinds. An investigator needs to be mindful about how each media stores data differently. For example, while data in the unused space on an HDD is stored as long as new data is not written, the data in the unused space of a SSD is destroyed within minutes of switching it on. This difference in retaining data makes it difficult to obtain a forensically sound image and recovering data (see checklist: An Agenda for Action for Data Recovery).

An Agenda for Action for Data Recovery

The cyber forensic specialist should ensure that the following provisional list of actions for data recovery are adhered to (check all tasks completed):

_____**1.** Make sure you are ready and have procedures in place for disasters like floods, tornadoes, earthquakes, and terrorism when they strike.

_____**2.** Make sure you are ready and have a plan in place to take periodic image copies and send them offsite.

_____**3.** Perform change accumulation to reduce the number of logs required as input to the recovery, which saves time at the recovery site. However, performing this step consumes resources at the home site.

_____**4.** Evaluate your environment to decide how to handle the change accumulation question/problem in action/task 3.

_____**5.** Make sure you have procedures in place to implement your plan.

_____**6.** Check your assets to make sure they're ready as part of your plan.

_____**7.** Make sure you build your recovery Job Control Language (JCL) correctly. JCL is tricky, and you need to get it exactly right. Data integrity and your business rely on this task.

_____**8.** Make sure you clean your RECON data sets. It can take hours if done manually, and it's an error-prone process. When your system is down, can you afford to make mistakes with this key resource?

_____**9.** Make sure you test your plan. There's a lot to think about. In the real world, there's much more.

_____**10.** Make sure your plan works before you are required to use it!

_____**11.** Make sure you have procedures in place to deal with issues of increased availability, shrinking expertise, and growing complexity, failures of many types, and the costs of data management and downtime.

Disk Geometry Components

With regard to HDD geometry, the surface of each HDD platter is arranged in concentric magnetic tracks on each side. To make accessing data more efficient, each track is divided into addressable sectors or blocks as seen in Figure 34.2. This organization is known as formatting. Sectors typically contain 512 bytes or 2048 bytes of data in addition to the address information. Newer HDDs use 4096 byte sectors. The HDD controller uses the format and address information to locate the specific data processed by the operating system.

Now, with regard to SSD geometry: Compared to HDDs, SSDs store data in 512-kilobyte sectors or blocks, which are in turn divided into 4096-byte long pages. These structures are located in arrays of NAND (Negated AND or NOT AND) transistors.

Inspecting Windows File System Architectures

File systems, including Windows, can be defined in six layers: Physical (absolute sectors), data classification (partitions), allocation units (clusters), storage space management (FAT or MFT), and information classification (folders), and application level storage (files). Knowing these layers will guide the investigator as to what tool is needed to extract information from the file system. Windows file systems have gone through an evolution starting from FAT and continuing to NTFS.

FAT (File Allocation Table)

FAT has been available widely on Windows systems starting with the MS-DOS operating system. This file system's incarnations include FAT12, FAT16, FAT32, and exFAT. The volume is organized into specific-sized chunks based on the version numbering of the file system. FAT12 has a cluster size of 512 bytes to 8 kilobytes, whereas FAT16 has cluster sizes ranging from 512 bytes to 64 kilobytes. FAT32 file systems can support disk sizes up to 2 terabytes using cluster sizes ranging from 512 bytes to 32 kilobytes. FAT file systems begin with the boot sector and proceed with FAT areas 1 and 2, the root directory, files and other directories. FAT provides a table to the operating system as to which cluster in the volume is used for a file or folder. In a FAT file system, file deletion is accomplished by overwriting the first character of the object's name with 0xE5 or 0×00 and by setting the table entry of the related clusters to zero. FAT file times are stored by using the local system's time information.

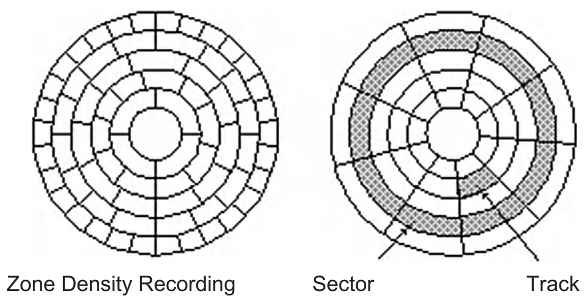

FIGURE 34.2 Physical structure of a drive.

New Technology File System (NTFS)

As the name suggests, NTFS was developed to overcome the limitations inherent in the FAT file system. These limitations were the lack of access control lists (ACLs) on file system objects, journaling, and compression, encryption, named streams, rich metadata, and many other features. The journaling features of NTFS make it capable of recovering itself by automatically restoring the consistency of the file system when an error takes place [1]. It also should be noted that NTFS file times are stored in the Universal Coordinated Time (UTC) compared to FAT where the operating system's local time is used. There are mainly two artifacts in NTFS that interests a forensics investigator: MFT (master file table) and ADS (alternate data streams).

Master File Table (MFT) MFT or $MFT can be considered one of the most important files in the NTFS file system. It keeps records of all files in a volume, the files' location in the directory, the physical location of the files on the drive, and file metadata. The metadata includes file and folder create dates, entry modified dates, access dates, last written dates, physical and logical file size, and ACLs of the files. The file and directory metadata is stored as an MFT entry that is 1024 bytes in size. The first 16 entries in the MFT belong to system files, such as the MFT itself. From a forensics investigator's perspective, entries are very interesting because when a file is deleted an entry gets marked as unallocated while the file content on the drive remains intact. The file name in the MFT entry can be overwritten due to MFT tree structure reorganization, so most of the time file names are not maintained. File data eventually is overwritten as the unallocated drive space gets used.

Alternate Data Streams (ADS) NTFS supports multiple data streams for files and folders. Files are composed of unnamed streams that contain the actual file data besides additional named streams (mainfile.txt:one-stream). All streams within a file share the file's metadata, including file size. Since the file size does not change with the addition of ADSs, it becomes difficult to detect their

existence. Open source forensics tools, such as The Sleuth Kit (TSK), can be used to parse MFT entries and reveal the existence of ADSs. Specifically, the TSK command fls can be used to list the files and the associated ADSs.

Locating and Restoring Deleted Content

Depending on the method of deletion, time elapsed since the deletion, and drive fragmentation; files can be fully or partially recovered. A deleted or unlinked file is a file whose MFT entry has been marked as unallocated and is no longer present in the user's view. The file can be recovered based on the metadata still present in the MFT entry, given that too much time has not passed since the deletion. The Sleuth Kit (TSK) can be used to parse the MFT to locate and recover these files. The investigator would need to execute the command fls to get a listing of the deleted file's inode and use that inode to extract the file data with the command icat.

Orphaned files' MFT entries on the one hand are no longer fully intact, and therefore the related metadata, such as file name might not be available. On the other hand, the file's data may still be recovered using the same method employed for deleted files.

Unallocated files' MFT entries have been reused and/or unlinked. In this scenario, the only way to recover the file would be to "carve" the data out of the unallocated drive space. Carving involves using tools (foremost, scalpel) that recognize specific file formats, such as headers and footers to find the beginning and end of the file and extract the data.

Overwritten files' MFT entries and content have been reallocated or reused. Complete recovery would not be possible. Fragments of the file can be recovered by searching through the unallocated spaces on the drive with tools, such as grep.

5. INVESTIGATING INFORMATION-HIDING TECHNIQUES

Hidden data can exist due to regular operating system activities or deliberate user activities. This type of data includes alternate data streams, information obscured by malicious software, data encoded in media (steganography), hidden system files, and many others.

Uncovering Hidden Information

Collection of hidden data can be a challenge for an investigator. The investigator needs to be aware of the different data-hiding techniques to employ the proper tools.

Scanning and Evaluating Alternate Data Streams

Open-source forensics tools, such as The Sleuth Kit (TSK), can be used to parse MFT entries and reveal the existence of ADSs. Specifically, the TSK command fls can be used to list the files and the associated ADSs as seen in Table 34.2.

In the example above, we can see that the file ads-file.txt contains two streams named suspicious.exe and another-stream. The numbers seen in the beginning of each listing is the inode. This value identifies each file and folder in the file system. We should note that 63 bytes were skipped starting from the beginning of the drive since that data belongs to the master boot record (MBR). To extract the file data from the file system, the TSK command icat can be used in combination with the inode values, as seen in Table 34.3.

Executing Code from a Stream

Malicious software can attempt to hide its components in ADSs to obscure themselves from investigators. Such components could be executable files. Executable ADSs can be launched with the Windows start command or by other scripting languages, such as VBScript or Perl by referring to the ADS file directly: start ads-file.jpg:suspicious.exe. Executable hidden in ADSs can be automatically launched on system start-up by defining it to do so in the Windows registry key "HKEY_LOCAL_MACHINE\Software\Microsoft\Windows\CurrentVersion\Run" by creating a string value containing the full path of the ADS file.

Steganography Tools and Concepts

Steganography is the science of hiding secret messages in nonsecret messages or media in a manner that only the

TABLE 34.2 Listing Files from a Raw Disk Image.

```
$fls–o 63-rp evidence-diskimage.dd
r/r 11315-158-1: ads-folder/ads-file.txt
r/r 11315-158-4: ads-folder/ads-file.txt:suspicious.exe
r/r 11315-158-3: ads-folder/host.txt:another-stream
```

TABLE 34.3 Extracting a File from a Raw Image with its Inode.

```
$ icat –o 63 evidence-diskimage.dd 11315-158-4 >
suspicious.exe
```

person who is aware of the mechanism can successfully find and decode it. Messages can be hidden in images, audio files, videos, or other computer files without altering the actual presentation or functionality. While steganography is about hiding the message and its transmission, cryptography only aims to obscure the message content itself through various algorithms. Steganography can be performed by using the least significant bits in image files, placing comments in the source code, altering the file header, spreading data over a sound file's frequency spectrum, or hiding encrypted data in pseudorandom locations in a file. Several tools perform steganography:

- S-Tools is a freeware steganography tool that hides files in BMP, GIF, and WAV files. The message can be encrypted with algorithms, such as IDEA, DES, 3DES, and MDC before being hidden in the images.
- Spam Mimic is a freeware steganography tool that embeds messages in spam email content. This tool would be useful when real spam messages are numerous and the fake spam message would not wake any suspicion.
- Snow is a freeware steganography tool that encodes message text by appending white space characters to the end of lines. The tool's name stands for and exploits the steganographic nature of whitespace. It also can employ ICE encryption to hide the content of the message in case of the detection of steganography. While most of the time it's visually undetectable, it can be discovered by a careful investigator or a script looking for this tool's artifacts.
- OutGuess is an open-source tool that hides messages in the redundant bits of data sources. OutGuess can use any data format as a medium as long as a handler is provided.

Detecting Steganography

During an incident, an investigator might suspect that steganography has been used by the suspect due to an admission, a discovery of specific tools, or other indicators. Traces of the use of steganography tools can be found in the recently used files (MRU) key, the USERASSIST key, and the MUICache key in the Windows registry; prefetch files, Web browser history, deleted file information in the file system; and in the Windows Search Assistant utility. File artifacts generated by these tools can also be a good indicator of the tools' use.

The presence of files (JPEG, MP3) that present similar properties, but different hash values, might also generate suspicion. The investigator might be able to discover such pairs of carrier and processed files to apply discovery algorithms to recover the hidden messages. Steganalysis tools can also be used to detect the presence of steganography:

- Stegdetect is an open-source steganalysis tool that is capable of detecting steganographic content in images that have been generated by JSteg, JPHide, Invisible Secrets, OutGuess, F5, Camouflage, and appendX.
- StegSpy is a freeware steganalysis tool that can currently identify steganography generated by the Hiderman, JPHideandSeek, Masker, JPegX, and Invisible Secrets tools.
- Stegbreak is used to launch dictionary attacks against JSteg-Shell, JPHide, and OutGuess 0.13b-generated messages.

Scavenging Slack Space

File slack or slack space refers to the bytes between the logical end of a file and the end of the cluster in which the file resides. Slack space is a source of information leak, which can result in password, email, registry, event log, database entries, and word processing document disclosures. File slack has the potential of containing data from the system memory. This can happen if a file can't fill the last sector in a cluster and the Windows operating system uses randomly selected data from the system memory (RAM slack) to fill the gap. RAM slack can contain any information loaded into memory since the system was turned on. The information can include file content resident in memory, usernames and passwords, and cryptographic keys. File slack space can also be used to hide information by malicious users or software, which can become challenging if the investigator is not specifically looking for such behavior. Volume slack is the space that remains on a drive when it's not used by any partition. This space can contain data if it was created as a result of deleting a partition. While the partition metadata no longer exists, its contents still remain on the drive. Partition slack is the area between the ending of a logical partition and the ending of a physical block in which the partition is located. It is created when the number of sectors in a partition is not a multiple of the physical block size. Registry slack is formed when a registry key is deleted and the size value is changed to a positive value. Normally, key sizes are negative values when read as signed integers. The registry key data still remains on the drive. Jolanta Thomassen created a Perl script called "regslack" to parse registry hives and extract deleted keys by exploiting the negative to positive conversion information.

Inspecting Header Signatures and File Mangling

Users or malware with malicious intent can alter or mangle file names or the files themselves to hide files that are used to compromise systems or contain data that has been gathered as a result of their malicious actions. These techniques include but are not limited to renaming files, embedding malicious files in regular files (Pdf, Doc, Flash), binding multiple executable in a single executable, and changing file times to avoid event time-based analysis. For example, a malicious Windows executable "bad.exe" can be renamed "interesting.pdf" and be served by a Web page to an unsuspecting user. Depending on the Web browser, the user would get prompted with a dialog asking whether the user would like to run the program; and most of the time the user will dismiss the dialog by clicking the OK button. To analyze a file disguised in different file extensions, a header-based file-type checker, such as the Linux "file" command or the tool TrID (also available in Windows), can be used. Table 34.4 presents a sample of the malware Trojan.Spyeye hidden in a file with an Acrobat Pdf document extension being detected by the tool file.

Combining Files

Combining files is a very popular method among malware creators. Common file formats, such as Microsoft Office files and Adobe Pdf and Flash files, can be used as containers to hide malicious executables. One example is a technique where a Windows executable is embedded in a PDF file as an object stream and marked with a compression filter. The stream is usually obfuscated with XOR. The Metasploit Framework provides several plug-ins to generate such files for security professionals to conduct social engineering in the form of phishing attacks. The example in Table 34.5 uses Metasploit to generate a Pdf file with an embedded executable file.

TABLE 34.4 Inspecting File Headers.

```
$ file hidden.pdf
hidden.pdf: PE32 executable for MS Windows (GUI)
Intel 80386 32-bit
```

```
Example of a PDF Header:
0000000: 2550 4446 2d31 2e36 0a25 e4e3 cfd2 0a31 %
PDF-1.6.%.....1
```

```
Example of a Windows Executable Header:
0000000: 4d5a 9000 0300 0000 0400 0000 ffff 0000
MZ..............
```

To discover such embedding, an investigator can use Didier Stevens's tool Pdf-parser to view the objects in a Pdf file.

Binding Multiple Executable Files

Binding multiple executable files provides the means to pack all dependencies and resource files a program might need while running into a single file. This is advantageous since it permits a malicious user to leave a smaller footprint on a target system and makes it harder for an investigator to locate the malicious file. Certain tools, such as the WinZip Self-Extractor, nBinder or File Joiner can create one executable file by archiving all related files whose execution will be controlled by a stub executable. When executed, the files will be extracted, and the contained program will be launched automatically. Some of these file binders can produce files that can't be detected by some anti-viruses, and if downloaded and run by an unsuspecting user, it can result in a system compromise.

File Time Analysis

File time analysis is one of the most frequently used techniques by investigators. File times are used to build a storyline that could potentially reveal how and when an event on a system caused a compromise. The file time of a malicious executable could be linked to a user's browser history to find out which sites were visited before the compromise occurred.

The problem with this type of analysis is that sometimes the file times can be tampered with and can't be relied upon as evidence. The tool Timestomp, created by James Foster and Vincent Liu, allows for the deletion or modification of file MACE times (modified, accessed, created, entry modified in MFT times) in the MFT's $STANDARD_INFORMATION attribute. Timestomp

TABLE 34.5 Creating a Malicious PDF file with the Metasploit Framework.

FIGURE 34.3 Changing timestamps as a result of time stomping.

can't change the file MACE times in the MFT's $FILE_NAME attribute because this attribute is meant to be modified by Windows system internals only. This time-tampering method can be defeated by using Mark McKinnon's MFT Parser tool to view all eight file times to detect discrepancies, as seen in Figure 34.3.

Executable compile times can also be used as a data point during timeline analysis. The open-source Python module pefile can be used to extract this information from the executable header. For example, if malicious software changes MACE times to a future date, but keeps its original compile time, this can be flagged as suspicious by an investigator as seen in Table 34.6.

TABLE 34.6 Compilation Time of an Executable Extracted with Pefile.

Compilation timedatestamp: 2010-03-23 23:42:40
Target machine: 0 × 14C (Intel 386 or later processors and compatible processors)
Entry point address: 0 × 000030B1

6. SCRUTINIZING EMAIL

Although many noncommercial users are favoring Webmail nowadays, most corporate users are still using local email clients, such as Microsoft Outlook or Mozilla Thunderbird. Therefore, we should still look at extracting and analyzing email content from local email stores. Email message analysis might reveal information about the sender and recipient, such as email addresses, IP addresses, data and time, attachments, and content.

Investigating the Mail Client

An email user will generally utilize a local client to compose and send his or her message. Depending on the user's configuration, the sent and received messages will exist in the local email database. Deleted emails can also be stored locally for some time depending on the user's preferences. Most corporate environments utilize Microsoft Outlook. Outlook will store the mail in a PST (portable storage table) or OST (offline storage table) format. Multiple PST files can exist in various locations on the user's file system and can provide valuable information to an investigator about the user's email specific activity.

Interpreting Email Headers

Generally speaking, email messages are composed of three sections: header, body, and attachments. The header contains source and destination information (email and IP addresses), date and time, email subject, and the route the email takes during its transmission. Information stored in a header can either be viewed through the email client or through an email forensics tool, such as libpff (an open-source library to access email databases), FTK, or EnCase.

TABLE 34.7 An Email Header.

Return-Path: <example_from@acme.edu>
X-SpamCatcher-Score: 1 [X]
Received: from **[1.1.1.1]** (HELO acme.edu)
  by fe3.acme.edu (CommuniGate Pro SMTP 4.1.8)
  with ESMTP-TLS id 61258719 for example_to@mail.acme.
edu; Mon, 23 Aug 2004 11:40:10 -0400
Message-ID: <4129F3CA.2020509@acme.edu>
Date: Mon, 23 Aug 2005 11:40:36 -0400
From: Jim Doe <example_from@acme.edu>
User-Agent: Mozilla/5.0 (Windows; U; Windows NT 5.1;
en-US; rv:1.0.1) Gecko/20020823 Netscape/7.0
X-Accept-Language: en-us, en
MIME-Version: 1.0
To: John Doe <example_to@mail.acme.edu>
Subject: Sales Development Meeting
Content-Type: text/plain; charset = us-ascii;
format = flowed
Content-Transfer-Encoding: 7bit

The "Received" line in Table 34.7 shows that the email was sent from IP address 1.1.1.1. An investigator should not rely on this information as concrete evidence because it can be easily changed by a malicious sender (email spoofing). The time information in the header might also be incorrect due to different time zones, user system inaccuracies, and tampering.

Recovering Deleted Emails

While most users treat emails as transient, the companies they work for have strict data retention policies that can enforce the storage of email, sometimes indefinitely. User emails usually are stored in backup archives or electronic-discovery systems to provide means for analysis in case there is an investigation. The email servers also can keep messages in store, although the users remove them from their local systems. Therefore, nowadays it has become somewhat difficult for a corporate user to delete an email permanently. Recovery is usually possible from various backup systems. In cases where there is no backup source and users delete an email from their local system, we need to perform several steps on the user's storage drive, depending on the level of deletion:

- If the user deletes the message, but does not empty the deleted messages folder, the user can move the messages from the deleted folder to the original folder quite easily.
- If the user deletes the email message and removes it from the deleted messages folder, then the investigator needs to apply disk forensics techniques to recover the email. In case of a Microsoft Outlook PST file, when a message is deleted it is marked as deleted by Outlook and the data remains on the disk unless the location on the drive is overwritten by new data. Commercial tools, such as AccessData's FTK or Guidance's EnCase, can be used to recover deleted messages. Another approach would be to use Microsoft's "Scanpst.exe" tool. To apply this technique, the investigator should first back up the PST and then deliberately corrupt the PST file with the command "DEBUG <FILE.pst> -f 107 113 20 −q." If the file is too large and there is insufficient system memory, then the investigator should use a hex editor to make the changes marked in red in the PST file as shown in Figure 34.4.

Once the PST file has been corrupted, then the "Scanpst.exe" tool should be located on the drive. And it should also be executed to repair the file, as seen in Figure 34.5.

7. VALIDATING EMAIL HEADER INFORMATION

Email header information can be tampered with by users who do not wish to disclose their source information or by malicious users who would like to fake the origin of the message to avoid detection and being blocked by spam filters. Email header information can be altered by spoofing, by using an anonymizer (removes identifying information), and using a mail relay server.

```

```

FIGURE 34.4 Manipulating a PST file for recovery.

Detecting Spoofed Email

A spoofed email message is a message that appears to be from an entity other than the actual sender entity. This can be accomplished by altering the sender's name, email address, email client type, and/or the source IP address in the email header. Spoofing can be detected by looking at the "Received:" and "Message-ID:" lines of the header. The "Received:" field will have each email server hop the message has taken before it has been received by the email client. An investigator can use the email server IP addresses in the header to get their hostnames from their DNS records and verify them by comparing to the actual outgoing and incoming email servers' information. The "Message-ID:" field uniquely identifies a message and is used to prevent multiple deliveries. The domain information in the "Message-ID:" field should match the domain information of the sender's email address. If this is not the case, the email is most probably spoofed. An investigator should also look out for different "From:" and "Reply-To:" email addresses and unusual email clients displayed in the "X-Mailer:" field.

Verifying Email Routing

Email routing can be verified by tracing the hops an email message has taken. This can be accomplished by verifying the "Received" field information through DNS records and if possible obtaining email transaction logs from the email servers involved. The "Message-ID" information can be searched for in the logs to make sure that

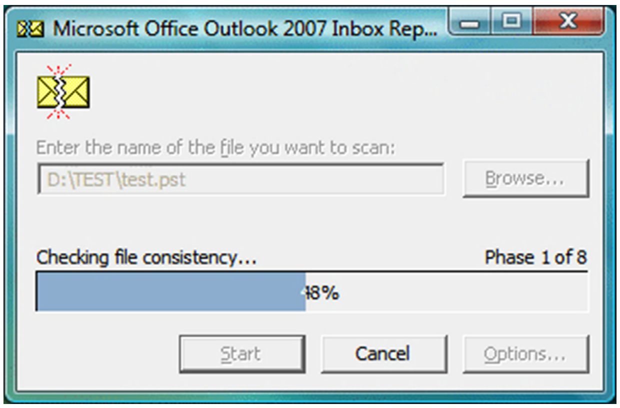

FIGURE 34.5 Use of the Scanpst.exe tool.

the message has actually traveled the route declared in the "Received" field.

8. TRACING INTERNET ACCESS

Knowing the path a perpetrator has taken becomes very valuable when an investigator is building a case to present in court. It adds credibility to the claim and solidifies the storyline by connecting the events. For example, knowing the path an attacker has taken to steal a company's source code can reveal the extent of the compromise (loss of domain credentials, customer information leakage, and intellectual property loss), show intent, and prevent the same attack from happening. Tracing Internet access can also be valuable in the case of employees viewing content that is not compliant with workplace rules.

Inspecting Browser Cache and History Files

An investigator can use various data points to trace a perpetrator's activity by analyzing the browser cache and Web history files in the gathered evidence. Every action of a user on the Internet can generate artifacts. The browser cache contains files that are saved locally as a result of a user's Web browsing activity. The history files contain a list of visited URLs, Web searches, cookies, and bookmarked Web sites. These files can be located in different folders, depending on the operating system (OS), OS version, and browser type.

Exploring Temporary Internet Files

A browser cache stores multimedia content (images, videos), and Web pages (HTML, JavaScript, CSS) to increase the load speed of a page when viewed the next time. For the Internet Explorer Web browser on Windows XP and 2003, the cache files can be located in the folder "Documents and Settings\%username%\Local Settings \Temporary Internet Files"; in Windows Vista/7/2008, they are located in the folder "Users\%username%\AppData\ Local\Microsoft\Windows\Temporary Internet Files":

- On Windows XP/2003 Firefox stores the cached files in the folder "C:\Documents and Settings\%username\Local Settings\ Application Data\Mozilla\Firefox\Profiles", and for Windows Vista/7/2008 in "C:\Users\%username% \AppData\Roaming\Mozilla\Firefox\ Profiles."
- On Windows XP/2003 Google chrome Web browser stores the cached files in the folder "C:\Documents and Settings\%username\Application Data\ Google \Chrome\Default\Cache", and for Windows Vista/7/ 2008 in "C:\Users\%username%\AppData\Local \Google\Chrome\ Default\Cache".
- The MAC times of these cached files can be used during a timeline analysis to find when certain artifacts, such as malware, get dropped by malicious or compromised Web sites. Malicious executable, Pdf files, or Java files can be located in the cache unless the cache is cleared by the user or malware.

Visited URLs, Search Queries, Recently Opened Files

The Internet Explorer Web browser stores the visited URL, search query, and opened file information in the file "index.dat," accompanied by last modified and last accessed, and expiration times. This file on Windows XP/ 2003 systems can be located in the folder "Documents and Settings\%username%\Local Settings\Temporary Internet Files\Content.IE5," and in Windows Vista/7/2008 systems, it is located in the folder "Users\%username% \AppData\ Local\Microsoft\Windows\Temporary Internet Files\Content.IE5," The "index.dat" file contains a LEAK record, which is a record that remains when it's marked as deleted, but can't be deleted due a related temporary Internet file (TIF) still being used.

Mozilla Firefox stores the URL, search, and open files-related history in a SQLite 3 database file Places. sqlite. These files on Windows XP/2003 systems can be located in the folder "C:\Documents and Settings\%username\Local Settings\ Application Data\Mozilla\Firefox \Profiles," and in Windows Vista/7/2008 systems, it is located in the folder "C:\Users\%username%\AppData \Roaming\Mozilla\Firefox\Profiles."

Google Chrome also stores its user activity data in SQLite 3 database files. These files on Windows XP/ 2003 systems can be located in the folder "C:\Documents and Settings\%username\Application Data\ Google \Chrome\default," and in Windows Vista/7/2008 systems, it is located in the folder "C:\Users\%username% \AppData\Local\Google\Chrome\ default."

All three browsers' history files, cookies, and cache files can be parsed and interpreted by log2timeline, a tool created by Kristinn Gudjonsson. log2timeline is capable of parsing multiple data sources and producing a timeline with, including but not limited to, file MAC times, registry write times, and Windows event logs. The tool can be pointed to a raw drive image (dd image), and as a result it can produce a "super" timeline in CSV format for all pursuable time-based data sources, as seen Figure 34.6 and Table 34.8.

Researching Cookie Storage

Internet Explorer cookies can be found in the folder "Documents and Settings\%username%\ Cookies" in Windows XP/2003 systems, and in Windows Vista/7/2008 systems, in "Users\%username%\AppData\Roaming\ Microsoft\Windows\Cookies." The cookies are stored in plaintext format.

FIGURE 34.6 log2timeline GUI.

TABLE 34.8 Using log2timeline from the Command Line.

log2timeline -p -r -f win7 -z EST5EDT /storage/disk-image001.dd -w supertimeline001.csv

Mozilla Firefox stores its cookies in a SQLite 3 database Cookies.sqlite located in the folder "C:\Documents and Settings\%username\Local Settings\ Application Data \Mozilla\Firefox\Profiles," and, in Windows Vista/7/2008 systems, it is located in the folder "C:\Users\%username %\AppData\Roaming\Mozilla\Firefox\Profiles".

Google Chrome stores its cookies in a SQLite 3 database file "C:\Documents and Settings\%username \Application Data\ Google\Chrome\default\Cookies" in Windows XP/2003 systems and in the file "C:\Users\%username%\AppData\Local\Google\Chrome\default\Cookies" in Windows Vista/7/2008 systems. The cookies files of all three browser types can be parsed and viewed by the tool log2timeline, as previously mentioned.

Reconstructing Cleared Browser History

It is possible to come across cleared browser histories during an investigation. The user could have deliberately deleted the files to hide their Web browsing activity, or a malware could have removed its traces to avoid detection and analysis. Nevertheless, an investigator will look into various locations on the suspect system to locate the deleted browser history files. The possible locations are unallocated clusters, cluster slack, page files, system files, hibernation files, and systems restore points. Using AccessData's FTK Imager on the suspect drive or drive image, an investigator can promptly locate the orphaned files and see if the browser files are present there. The next step would be to use the FTK Imager to look at the unallocated spaces, which should end up being a time-consuming analysis as seen in Figure 34.7. If the drive has not been used too much, an investigator has a high chance of locating the files in the unallocated space.

Auditing Internet Surfing

Knowing what employees are browsing on the Web while they are at work has become necessary to prevent employees from visiting sites that host malicious content (sites with exploits and malware), content that is not compliant with workplace rules, and content that is illegal. Employees can use the Web to upload confidential corporate information, which can cause serious problems for the employer.

Tracking User Activity

User activity can be tracked by using tools that monitor network activity, DNS (Domain Name Server) requests, local user system activity, and proxy logs. Network activity, on the other hand, can be monitored by looking at netflows. Netflow is a network protocol developed by Cisco Systems for monitoring IP traffic. It captures source and destination IP addresses, IP protocol, source and destination ports, and IP types of service.

Local user system activity can be monitored by installing specific agents on the users' systems that can report their activity back to a centralized server. SpectorSoft offers a product called Spector 360 that can be installed on a user system and a central server. The agents on the user systems can track user browser activity by hooking into system APIs and enforce rules set by the employer.

DNS requests can be monitored at the corporate DNS server level or by looking at network traffic. When a user requests a Web page with its domain name, the name gets translated to an IP address via DNS. User activity can be tracked by monitoring for domains that are not approved by the employer or domains hosting illegal content in the DNS server's logs.

Most corporate environments utilize a proxy server to funnel Web traffic through. A proxy server acts as the middle-man for requests from users seeking resources from external servers. This position of the proxy server permits tracking user browsing activity and can be used to filter or block certain behavior. Content protected by SSL (Secure Socket Layer protocol) can also be tracked by proxies, by setting the proxy up as an intercept proxy.

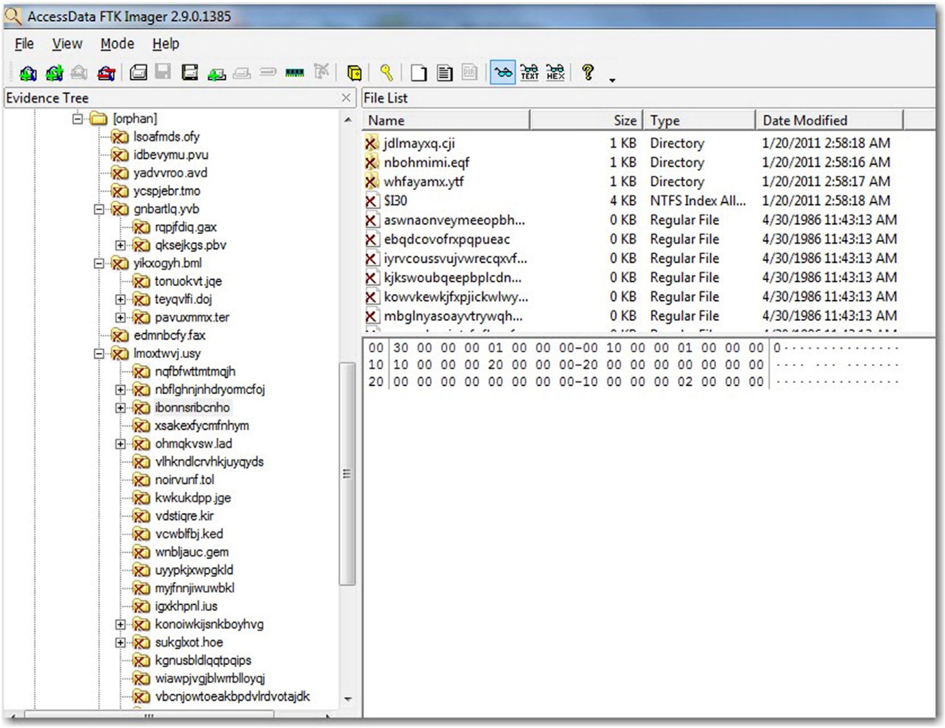

FIGURE 34.7 Use of AccessData FTK Imager.

Squid is one of the most popular open-source proxies available and can carry out the necessary functions to track and block user activity.

Uncovering Unauthorized Usage

Unauthorized Web usage can take multiple forms, such as downloading or viewing noncompliant or illegal content, uploading confidential information, launching attacks on other systems, and more. Once the unauthorized usage has been detected by the previously mentioned means, an investigator can focus on the user's system to corroborate the unauthorized activity. This can be done by analyzing browser history files and related file system activities. Building a "super" timeline with the tool log2timeline can become very useful to find the created cache and cookie files and the browser history entries around the same time the unauthorized activity was detected.

9. SEARCHING MEMORY IN REAL TIME

Analyzing memory in real time can provide very crucial information about the activities of malware or a hacker that would be otherwise unavailable if one were only looking at a system's drives. This information can be network connections and sockets, system configuration settings, collected private information (usernames, passwords, credit-card numbers), memory-only resident executables, and much more. Real-time analysis involves analyzing volatile content and therefore requires swift action by the investigator. The investigator has to quickly act to capture an image of the memory using tools, such as MoonSols Windows Memory Toolkit, GMG Systems' KnTDD, or F-response. F-response is different from the other memory-imaging tools since it provides real-time access to the target systems memory. Real-time access can reduce the time to analyze by permitting the investigator to analyze the memory right away without waiting for the whole memory to be downloaded into a file. You can read more about F-response at www.f-reponse.com.

Comparing the Architecture of Processes

Generally speaking, Windows architecture uses two access modes; user and kernel modes. The user mode includes application processes, such as programs and protected subsystems. The protected subsystems are so named because each of these is a separate process with its own protected virtual address space in memory. The kernel mode is a privileged mode of functioning in which the application has direct access to the virtual memory. This includes the address spaces of all user mode processes and applications and the associated hardware. The kernel mode is also called the protected mode, or Ring 0:

- Windows processes are generally composed of an executable program, consisting of initial code and data, a private virtual address space, system resources that are accessible to all threads in the process, a unique

identifier, called a process id, at least one thread of execution, and a security context (an access token).

- A Windows thread is what Windows uses for execution within a process. Without threads, the program used by the process cannot run. Threads consist of contents of the registers representing the state of the processor, two stacks (one for the thread for executing kernel-mode instructions, and one for user-mode), private storage area used by the subsystems, run-time libraries and DLLs (dynamic-link libraries), and a unique identifier named a thread ID.
- DLLs are a set of callable subroutines linked together as a binary file that can be dynamically loaded by applications that use the subroutines. Windows user-mode entities utilize DLLs extensively. Using DLLs is advantageous for an application since applications can share DLLs. Windows ensures that there is only one copy of a DLL in memory. Each DLL has its own import address table (IAT) in its compiled form.

Identifying User and Kernel Memory

Windows refers to Intel's linear memory address space as a virtual address space (VAS) since Windows uses the disk space structure to manage physical memory. In other words 2 GB of VAS is not a one-to-one match to physical memory. 32-bit Windows divides VAS into user space (linear addresses 0x00000000 − 0x7FFFFFFF, 2 GB) and kernel space (linear addresses 0x80000000—0xFFFFFFFF, 2 GB), where user space gets the lower end of the address range and kernel space gets the upper end. To get an idea of how user space is arranged, we can use the !peb command in the Windows debugger. A list of loaded kernel modules can be obtained by running the command 'lm n' in the Windows debugger.

Inspecting Threads

While it is assumed that user and kernel codes are restricted to their own address spaces, a thread can jump from user space to kernel space by the instruction SYSENTER and jump back with the instruction SYSEXIT. Malicious threads can also exist within valid kernel or other user processes. Such hidden or orphan kernel threads can be detected using the Volatility Framework with the plug-in threads, which are shown in Table 34.9.

Discovering Rogue DLLs and Drivers

DLLs can be used for malicious purposes by injecting them through AppInit_DLLs registry value, SetWindowsHookEx() API call, and using remote threads via the CreateRemoteThread() Windows API call. Injected DLLs can be detected using the Volatility Framework's apihooks plug-in. The plug-in provides detailed information regarding the DLLs loaded, such as IAT, process, hooked module, hooked function, from-to instructions, and hooking module, as seen in Table 34.10.

The Volatility Framework plug-in malfind can find hidden or injected DLLs in user memory based on VAD (Virtual Address Descriptor) tags and page. Use of the malfind plug-in to discover injected code is shown in Table 34.11.

The plug-in dlllist in the Volatility Framework can also be used to list all DLLs for a given process in memory and find DLLs injected with the CreateRemoteThread and LoadLibrary technique. This technique does not hide the DLL and, therefore, will not be detected by the plug-in malfind, as seen in Table 34.12.

Employing Advanced Process Analysis Methods

Processes can be analyzed using tools, such as the Windows Management Instrumentation (WMI) and walking dependency trees.

TABLE 34.9 Use of the Plug-In Threads.

Evaluating Processes with Windows Management Instrumentation (WMI)

WMI is a set of extensions to the Windows Driver Model that provides an operating system interface where components can provide information and notifications. The WMI classes Win32_Process can help collect useful information about processes. The Windows command wmic extends WMI for operation from several command-

line interfaces and through batch scripts without having to rely on any other programming language. The command wmic uses class aliases to query related information. It can be executed remotely as well as locally by specifying target node or hostname and credentials. Various commands that can be used to extract various process-related information through wmic are shown in Table 34.13.

WMI output can be used to get a clean baseline of a system to periodically run comparisons. The comparisons can show any new process that has appeared on the system and can help to update the baseline if the new process is a known one.

Walking Dependency Trees

Viewing the dependencies of a process can provide valuable information about the functionality of a process. A process's dependencies may be composed of various Windows modules, such as executables, DLLs, OCX (object linking and embedding control extension) files, and SYS files (mostly real-mode device drivers). Walking a dependency tree means to explore a process's dependencies in a hierarchical view, such as a tree. The free tool Dependency Walker provides an interface that presents such a view, which is shown in Figure 34.8.

Figure 34.8 lists all of the functions that are exported by a given Windows module and the functions that are actually being called by other modules. Another view

TABLE 34.13 List of WMI Commands to Get Process Information.

wmic /node: /user: process where get ExecutablePath,parentprocessid	Find the path to a specific running executable and its parent process (for all, leave off 'where name = ').
wmic /node: /user: process where get name, processid,commandline,creationdate	Find command-line invocation of a specific executable, as well as the creation time for the process (for all, leave off "where name = ").
wmic startup list full	Find all files loaded at start-up and the registry keys associated with autostart.
wmic process list brief | find "cmd.exe"	Search for a specific process name, such as cmd.exe.

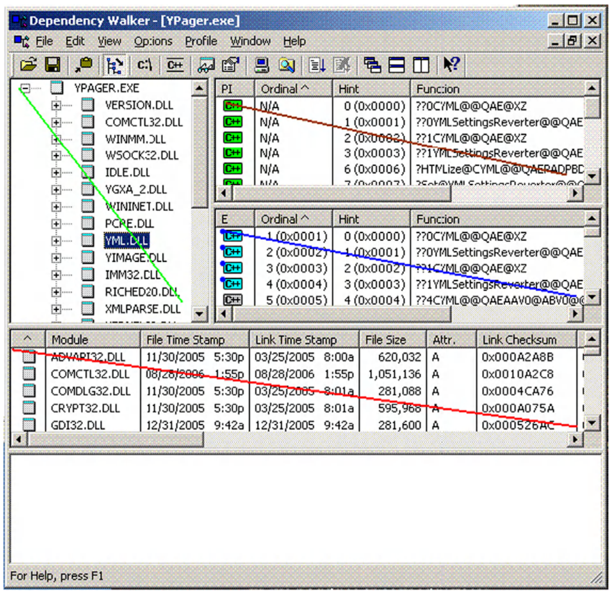

FIGURE 34.8 Using the dependency walker.

displays the minimum set of required files, along with detailed information about each file, including a full path to the file, base address, version numbers, machine type, and debug information. Dependency Walker can be used in conjunction with the tool Process Explorer (a free Microsoft tool) to detect malicious DLLs. This can be achieved by comparing the DLL list in Process Explorer to the imports displayed by the Dependency Walker.

Auditing Processes and Services

Auditing changes in process and service properties, as well as their counts on a system, can provide valuable information to an investigator about potentially malicious activity. Rootkits, viruses, trojans, and other malicious software can be detected by the auditing process and service creation or deletion across a period of time. This technique is frequently used in malware behavioral analysis in sandboxes. We can audit Windows processes and services by using tools that utilize system APIs or system memory for live analysis. To view information through the system APIs, we can use the tool Process Hacker. The Process Hacker provides a live view of processes and services that are currently being executed or are present on the system. It provides an interface to view and search process information in detail, such as process privileges, related users and groups, DLLs loaded, handles opened, and thread information, which is shown in Figure 34.9. Service information can also be viewed in the services tab. Process and service information can be saved periodically and compared across time to detect any suspicious variations.

System memory can also be analyzed with the Volatility Framework for audit purposes. Periodic memory samples can be obtained using tools, such as F-response, MoonSols Windows Memory Toolkit, or GMG Systems' KnTDD. The Volatility Framework plug-in pslist can be used to audit processes, while the plug-in svcscan can be used to audit services.

Investigating the Process Table

The process table (PT) is a data structure kept by the operating system to help context switching, scheduling, and other activities. Each entry in the process table, called process context blocks (PCBs), contains information about a process, such as process name and state, priority, and process id. The exact content of a context block depends on the operating system. For example, if the operating system supports paging, then the context block contains a reference to the page table. While to a user a process is identified by the process id (PID), in the operating system the process is represented by entries in the process table. The process control block is a large data structure that contains information about a specific process. In Linux this data structure is called task_struct, whereas in Windows it is called an EPROCESS structure. Each EPROCESS structure contains a LIST_ENTRY structure called ActiveProcessLinks, which contains a link to the previous (Blink) EPROCESS structure and the next (Flink) EPROCESS structure.

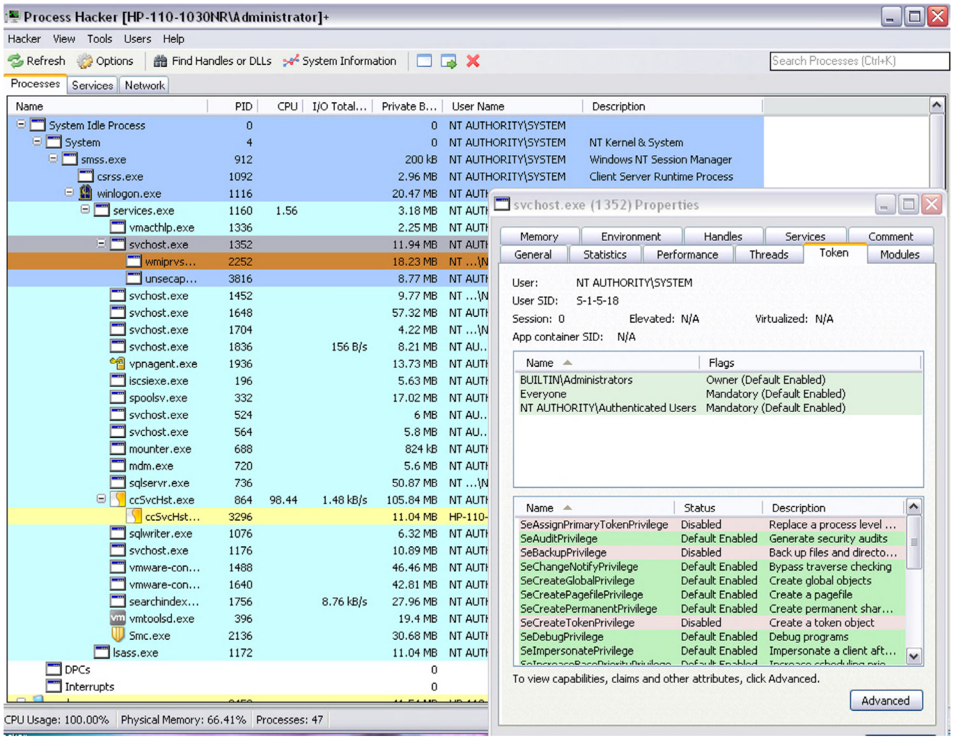

FIGURE 34.9 Using Process Hacker to view process and service information.

A listing of processes represented in the PT can be obtained by using the plug-in pslist in the Volatility Framework. This plug-in generates its output by walking the doubly-linked list. Certain malware or malicious users can hide processes by unlinking them from this linked list by performing direct kernel object manipulation (DKOM). To detect this kind of behavior, the Volatility Framework plug-in psscan can be used since it relies on scanning the memory to detect pools similar to that of an EPROCESS structure instead of walking the linked list.

Discovering Evidence in the Registry

We have already covered one method to inject code into a process. Another method is to add a value in the AppInit_DLLs registry key (HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Windows\AppInit_DLLs) that makes a new process to load a DLL of malicious origin.

AppInit_DLLs is a mechanism that allows an arbitrary list of DLLs to be loaded into each user mode process on the system. Although a code-signing requirement was added in Windows 7 and Windows Server 2008 R2, it is still being utilized by various malicious software to hide and persist on a system.

The Volatility Framework can also be used to analyze the registry that has been loaded to memory. The plug-ins that are available from the Volatility Framework for registry analysis are shown in Table 34.14.

TABLE 34.14 List of Volatility Framework Plug-Ins to extract Registry Information from Memory.

hivescan	finds the physical address of CMHIVE structures, which represent a registry hives in memory.
hivelist	takes a physical address of one CMHIVE, returns the virtual address of all hives, and their names
printkey	takes a virtual address of a hive and a key name (e.g., "ControlSet001\Control"), and display the key's timestamp, values, and subkeys.
hashdump	dump the LanMan and NT hashes from the registry.
lsadump	dump the LSA secrets (decrypted) from the registry.
cachedump	dump any cached domain password hashes from the registry.

A listing of services can be obtained from the registry in memory from the registry key "HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services." This key contains the database of services and device drivers that get read into the Windows service control manager's (SCM) internal database. SCM is a remote procedure call (RPC) server that interacts with the Windows service processes.

TABLE 34.15 List of Volatility Framework plug-ins to detect rootkit hooking.

Rootkit Technique	The Volatility Framework Plug-In
IAT (import address table) Hooks	Apihooks—detect overwritten IAT entry for a PE file
EAT (export address table) Hooks	apihooks
Inline API Hooks	apihooks
IDT (interrupt descriptor table) Hools	Idt—detects overwritten IDT entries that point to malicious interrupts or processor exceptions
Driver IRP (I/O request packets) Hooks	Driverirp—detects overwritten IRP function table entries (modified to monitor buffer data)
SSDT (system service descriptor table) Hooks	Ssdt—detects hooking of pointers to kernel mode functions in the SSDT that occurs per thread
Hiding with Orphan Threads in Kernel	Threads—detects orphan threads that can unlink or unload its driver

Other registry keys that might be of interest are the keys located in the registry key "HKEY_LOCAL_ MACHINE\ SOFTWARE\ Microsoft\ Windows\CurrentVersion." The keys that are part of the auto start registries are "Run," "RunOnce," "RunOnce\Setup," "RunOnceEx," "RunServices," and "RunServicesOnce." Malware can set values in these keys to persist across system restarts and get loaded during system start-up.

Deploying and Detecting a Rootkit

Rootkits are composed of several tools (scripts, binaries, configuration files) that permit malicious users to hide their actions on a system so they can control and monitor the system for an indefinite time. Rootkits can be installed either through an exploit payload or after system access has been achieved. Rootkits are usually used to provide concealment, command and control (C2), and surveillance. A rootkit will usually try to hide system resources, such as processes, Registry information, files, and network ports. API hooking is a popular rootkit technique that intercepts system calls to make the operating system report inaccurate results that conceal the presence of the rootkit. To skip all of the system-level subversion, we can look into the memory directly to detect rootkits. The Volatility Framework provides various plug-ins to detect rootkit concealment techniques, as seen in Table 34.15.

10. SUMMARY

In this chapter we have seen the importance of having a well-documented incident response plan and process, and having an incident response team that is experienced in cyber forensics analysis. Besides having these important components, an organization needs to have strong policies and procedures that back them. Incident response is not only about countering the incident, but also about learning from it and improving on the weaknesses exposed. We should always keep in mind that preparedness is paramount since it is a matter of when rather than if an incident will strike.

With regard to the near future, the amount of data that needs to be gathered and analyzed is increasing rapidly, and as a result we are seeing the emergence of big-data analytic tools that can process disparate data sources to deal with large cases. Tomorrow's incident response teams will need to be skilled in statistical analysis as well as forensics to be able to navigate in this increasingly hostile and expanding cyberspace. As you can see, incident response and cyber forensics needs to be a step ahead of the potential causes of threats, risks, and exploits.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Cyber forensics and incident response go hand in hand.
2. True or False? In an organization there is a daily occurrence of events within the IT infrastructure, but not all of these events qualify as incidents.
3. True or False? Forensic analysis is not usually applied to determine who, what, when, where, how, and why an incident took place.

4. True or False? When an incident response team comes across incidents relevant to these laws, they should consult with their legal team.
5. True or False? An organization should be prepared beforehand to properly respond to incidents and mitigate them in the longest time possible.

Multiple Choice

1. How do incident response and cyber forensics fit together?
   - **A.** They don't
   - **B.** Incident response helps cyber forensics in analyzing evidence
   - **C.** Cyber forensics provides answers to questions that need to be answered for proper incident response
   - **D.** None of the above
   - **E.** All of the above
2. Which option below might be classified as an incident?
   - **A.** Phishing attack
   - **B.** Unauthorized access
   - **C.** Intellectual property theft
   - **D.** Denial-of-service attack
   - **E.** All of the above
3. Which of these options should be considered volatile data and be captured immediately?
   - **A.** Configuration files
   - **B.** Database files
   - **C.** Documents
   - **D.** System Memory
   - **E.** All of the above
4. Which considerations would be involved in monitoring employee email?
   - **A.** Technical factors
   - **B.** Legal factors
   - **C.** Organizational factors
   - **D.** All of the above
   - **E.** None of the above
5. Which tool below can be used to extract the MFT of a Windows system from a drive?
   - **A.** The Sleuthkit
   - **B.** The Volatility Framework
   - **C.** The KntDD
   - **D.** Truecrypt
   - **E.** All of the above

EXERCISE

Problem

How does an organization ship its hard drives?

Hands-On Projects

Project

How does an organization get its data back?

Case Projects

Problem

As an exercise to practice what you have learned in this chapter, you will analyze your own Windows workstation:

1. Create an image of your disk drive and save it to an external drive using AccessData FTK Imager.
2. Create a memory sample from your system using MoonSols Windows Memory Toolkit and save it to an external drive.
3. Create a super timeline of the disk image using log2timeline and list the files created within 24 hours.
4. Using the Volatility Framework, get a list of the following objects from the memory sample: processes, DLLs, modules, services, connections, sockets, API hooks.

Optional Team Case Project

Problem

When should an organization consider using a computer forensic examiner?

Chapter 35

Securing e-Discovery

Scott R. Ellis, EnCE, RCA, RCIA
kCura Corporation

Few, if any, corporations are exempt from litigation. For some, the risk of litigation far outweighs the cost associated with managing and structuring their internal information systems in such a way as to facilitate discovery actions. In other words, the cost of doing "business as usual" in the event of large-scale litigation can actually bankrupt a company. Preparedness to respond swiftly and accurately to discovery requests can prevent costly processing and overly inclusive review. In the legal industry, any request for information typically arrives in the form of a court-ordered "discovery request." Essentially, when one organization sues another organization, they each are allowed to request the disclosure of any relevant documents relating to the litigated matter. For some corporations, these actions occur daily. For them, adhering to some sort of framework of security that allows them to quickly engage and respond to such requests becomes extremely important. There exist many models that outline and assist to define the entire process of electronic discovery, such as the Electronic Discovery Reference Model (EDRM).[1] This chapter does not aspire to redefine, reorganize, or even correct or suggest a need for correction in any such model.

The field of e-discovery relates to litigation as a whole (see checklist: An Agenda for Action for Discovery of Electronic Evidence). Most aspects of civil lawsuits will, at some point, brush up against the EDRM, whether they be civil or criminal. Recent years have seen deeper adoption and application of the Federal Rules of Civil Procedure (FRCP) by criminal courts as well. Cultivating an understanding of the FRCP therefore becomes a necessity for any attorney who wishes to practice law in the federal court system.

It follows then that corporations should also develop a similar, if not deeper, awareness of the EDRM life cycle. While this chapter acknowledges and makes reference to regulatory and legal compliance requirements, it does not seek to explain them or detail them. Such legal, risk, and compliance issues are going to be industry dependent. First on any e-discovery manager's list should be the need to discover whether or not data (and what data!) should be preserved beyond the scope of immediate purposefulness. Figure 35.1 presents the basic diagram of the EDRM life cycle.

When one organization sues another, they may become subject to a court requirement that they preserve any information pertaining to the matter. Even a letter from an opposing attorney requesting that the defendant secure and "hold" any documents that may pertain to the matter (and even in the case of a threatening letter that does not specifically request a hold when the circumstances indicate a reasonable likelihood of litigation) may trigger a need to preserve information, as litigation may be imminent. In the United States, the process of collecting, processing, reviewing, and producing this body, this collective corpus of "documents" that may contain email, images, executables, databases, text files, documents, spreadsheets, structured systems, and so on that may be relevant to the litigation is commonly called "discovery." Essentially, *anything*, any potentially relevant information that exists in electronic form, is fair game. Furthermore, in some industries, there may be regulatory compliance laws that dictate the length of time that data must be preserved. One such example is Sarbanes-Oxley, or SOX,[2] which states:

Whoever knowingly alters, destroys, mutilates, conceals, covers up, falsifies, or makes a false entry in any record, document, or tangible object with the intent to impede, obstruct, or influence the investigation or proper administration of any matter within the jurisdiction of any department or agency of the United States or any case filed under title 11, or in relation to or contemplation of any such matter or case, shall be fined under this title, imprisoned not more than 20 years, or both.

There are, in fact, *criminal* penalties for getting this wrong, in addition to civil monetary sanctions.

1. EDRM (edrm.net).

2. Section 802(a) of the SOX, 18 USC 1519.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00035-0

An Agenda for Action for Discovery of Electronic Evidence

The cyber forensics specialist should ensure the following are adhered to (check all tasks completed):

_____**1.** Do not alter discovered information.
_____**2.** Always back up discovered information.
_____**3.** Document all investigative activities.
_____**4.** Accumulate the computer hardware and storage media necessary for the search circumstances.
_____**5.** Prepare the electronic means needed to document the search.
_____**6.** Ensure that specialists are aware of the overall forms of information evidence that are expected to be encountered as well as the proper handling of this information.
_____**7.** Evaluate the current legal ramifications of information discovery searches.
_____**8.** Back up the information discovery file or files.
_____**9.** Start the lab evidence log.
_____**10.** Mathematically authenticate the information discovery file or files.
_____**11.** Proceed with the forensic examination.
_____**12.** Find the MD5 message digest for the original information discovery file or files.
_____**13.** Log all message digest values in the lab evidence log.
_____**14.** When forensic work is complete, regenerate the message digest values using the backups on which work was performed; log these new values alongside the hashes that were originally generated. If the new values match the originals, it's reasonable to conclude that no evidence tampering took place during the forensic examination of the information file(s).
_____**15.** Briefly compare the physical search and seizure with its logical (data-oriented) counterpart, information discovery.

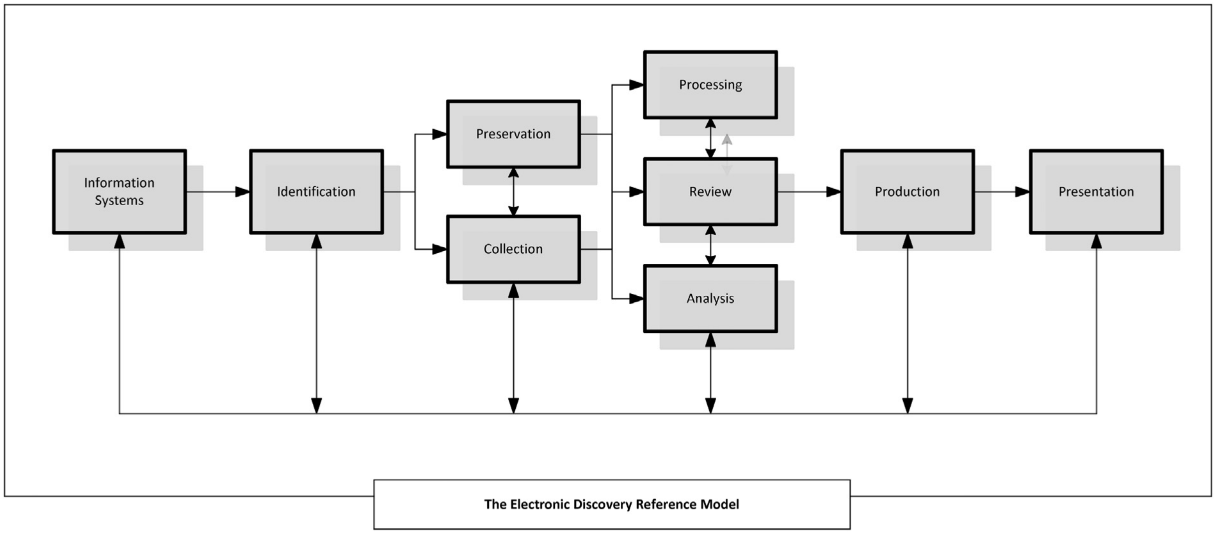

FIGURE 35.1 The Electronic Discovery Reference Model provides a loose framework for how to manage electronic discovery and what to expect from a process viewpoint.

Technologists should be aware that the regulations exist, and they should ensure that their organizations are compliant by working with a qualified law firm or legal department. There exist mountains of this sort of regulatory legalese. Whether or not it applies to your organization is important to the work and the level of security detailed in this chapter and to its implementation. Understanding all of the challenges of regulatory compliance in your organization will likely be a departmental or cross-departmental responsibility—that is, an entire department or team will provide oversight of this increasingly important aspect of conducting business.

The EDRM model, and its accompanying diagram, represent just *one* way of how data may flow from an information system to a discovery information system to a courtroom. The large box in Figure 35.2 represents the confines of a discovery information system. Shaded boxes represent zone boundaries where information may move

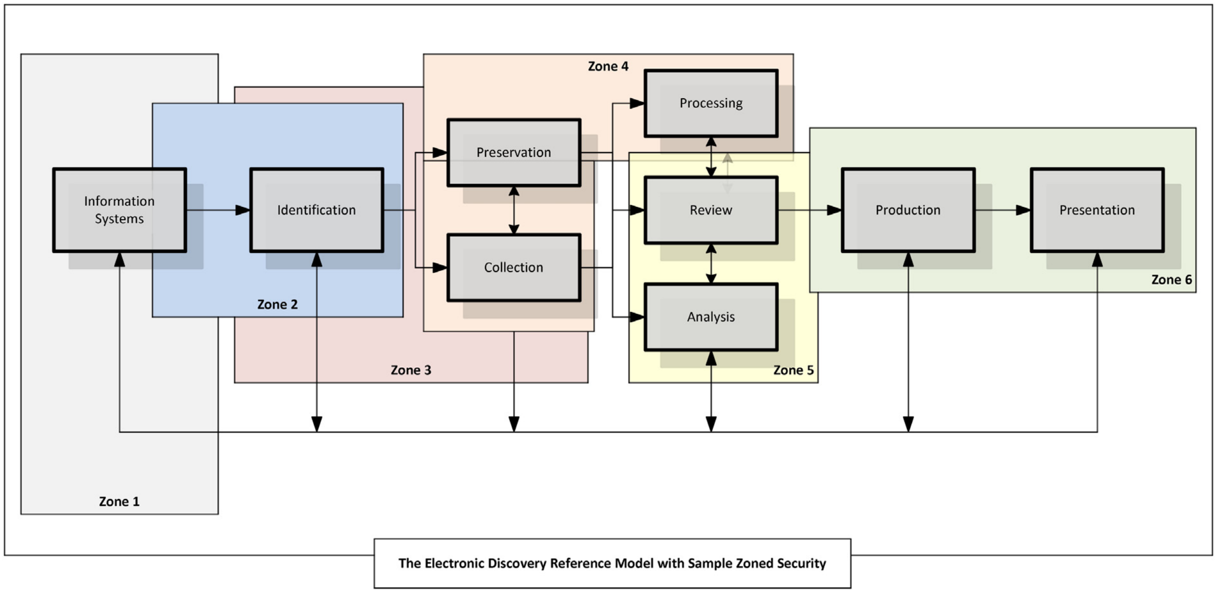

FIGURE 35.2 Underpinning the EDRM with zone security throughout the e-discovery life cycle.

from one vendor to another. Dotted line boxes are used to refer to areas of interest or to break out details or suggest technologies. In this example, overlapping zones identify areas of functionality where data is passed from one vendor to the next. Some vendors do service zones 1–6, but in this example, each zone represents a different vendor handling data. A similar, real diagram of a corporate EDRM would attach a similar diagram, complete with vendor names and data transfer protocols, to an EDRM procedure document for each and every case where data may be processed using different vendors. For security purposes, it is wisest to keep the number of vendors to a minimum, with set and established data conduits.

There are disparate, often overlapping, zones in this diagram because it is very common for multiple vendors to be involved in processing data in a lawsuit. This is done because very few vendors perform the work required in all zones. From start to finish, from standard information management strategies through to presenting data in the courtroom, few, if any, can do everything and do it well. Even fewer corporations manage any of this work internally. Later, this chapter will refer back to the numbers on the boxes and will describe the various security measures taken at each zone interface, as well as the benefits of shifting certain work to fewer vendors or moving certain tasks to internal, corporate IT. Some of this fragmentation can also be attributed to the defibrillating effect of the change in the Federal Rules on the entire paper discovery industry in 2006. Many of these small, e-discovery shops already existed, but were amped up by the sudden demand for their services. So, rather than using the EDRM as one (and perhaps the most accurate) example, this chapter:

1. Explains it from an industry insider perspective
2. Collates issues of performance, urgency, accuracy, risk, and security to a zoned model that underpins the EDRM
3. Explains the very real need for organizations to secure certain operations internally
4. Provides examples through real-world experiences of flawed discovery and what should have been done differently
5. Discusses how security *from* the information, as well as security *of* it, plays a critical role throughout much of the EDRM

1. INFORMATION MANAGEMENT

The framework of the EDRM begins with information management. Much in the same way that there exists a model for electronic discovery, there also exists an information governance reference model (IGRM) that pays particular attention to the needs of an IT management organization that concerns itself, and prepares itself, for possible future litigation. To be successful, information management must consider all the stakeholders in an environment; it must apply successful collaboration across all groups in an enterprise; it must consider the security of the data and protection of systems; and it must engage information technology to implement the procedures and guidelines created. It must also be secure. There is no worse feeling than the sinking sensation you

will feel than when @nonymous hacks your systems and posts your entire discovery database online, along with your CEO's email box.

2. LEGAL AND REGULATORY OBLIGATION

Certain types of organizations are more likely than others to be prone to litigation. This means that they must operate at a heightened sense of awareness as it pertains to e-discovery processes. In particular, law firms have both ethical and legal obligations to protect client confidential data. Guidelines pertaining to the security requirements and the specific safeguards required by law are all outlined in the Federal Rules of Civil Procedure. This chapter is not meant to replace that. Rather, this chapter seeks to familiarize its readers with the basic flow of information throughout a lawsuit so that proper security can be executed. Without knowledge and deep understanding of the inner workings of a lawsuit and the functions that are required for the successful management of it, security will surely fail.

Securing the Field of Play

This chapter is titled "Securing e-Discovery," but it has much broader reaching implications. Just about any organization may be subject to litigation. What, then, is a security model, if it is one that doesn't anticipate litigation? A security model that does not anticipate the possible need to collect large amounts of data, port it into other systems, and ensure that the data is relevant risks being unresponsive to a request from the court and possible noncompliance with an order from a judge. Much in the same way that not knowing the speed limit will not get you out of a ticket, not knowing how or where your data is stored will not prevent a judge from sending someone else to your offices to show you how your systems interoperate. This person will be an expert, probably chosen by the opposition, interviewed by the judge, and you will be paying his bill, which may be as much as $400/hr. or higher. What follows are several steps to:

- Assess, evaluate, and remediate the current state of security and discovery preparedness
- Get things in order
- Set the stage for data collection and effective response to a discovery request

Step 1: Examine the Information Management Environment

Are you secure? Your internal systems may be a mess of disparate data and IT fiefdoms, but first, let's close the doors and staunch the flow. Areas where sensitive data, or easily obtained access to sensitive data stores, should be secured are as follows:

- Physical security—Common areas, such as lunchrooms that may have external access, should never be unmanned. Reception areas that have front door access, or may have corridors that lead to other areas should also be secured with:
  - Biometric security for physical access to sensitive data areas
  - Background checks
  - Visible photo badge policy
  - Visitor policy that includes visible visitor photo ID badges
- Data center ISO 9001 security.
- Firewalls should be configured with the most minimal access possible.
- Antivirus should be nonintrusive and should be pointing at points of ingress. File repositories should run scheduled scans—virus signature databases are frequently updated, a file that is clean today may trip an alert after a signature update. Entire system scans should be scheduled jobs that run during nightly or weekly maintenance.
- Acceptable use policy—Users are the number one incursion vector. Ensure that your acceptable use policy is well formed and *understood.*
- Response plans (what do we do when someone we don't know tries to tailgate us into the office? What do we do when tables are suddenly missing in our database?)

Step 2: Measure: How Secure is the System?

Penetration testing should be performed against the enterprise systems. Any organization that wishes to conduct collections must understand that sensitive data will be copied and corraled into a new area. This area should be secured. If any one of the above steps is not followed, as an IT director you will almost certainly come into work and find that the penetration team has placed a chocolate cake on your desk and changed your desktop image. The organization that will conduct the penetration testing should be testing the following things:

1. Internal, physical penetration. Can they put someone at a desktop and access the system? Can they insert "malicious" code into your system? This may be as simple as accessing the BIOS of a machine, changing the boot order, and booting a new machine on your network.
2. Penetration testing of any and all external facing software, especially web sites.
3. Internal penetration testing—Can internal systems be breached by someone sitting at a desktop, with varying levels of access?
4. Penetration testing of any critical software as a service (SAAS) system. For example, if the testers can trick

the HR director into logging in to a spoofed or cross-site scripted payroll site that contains sensitive employee data, a flaw in your security system exists.

5. Penetration testing of known services that protect essential data. Ensure that they can't be hacked easily. Many of the methods for hacking services such as Amazon Cloud or ADP are easy to spot. All software as a service (SAAS) providers should have implemented or be in the process of implementing two-factor authentication. If they are not, then your data shouldn't be there and should be moved.
6. Examine the VLAN architecture, in both virtual and physical topologies. Virtual switches offer a whole host of challenges of which many IT administrators are unaware.
7. Socially engineered attacks—Most attacks have a social component. The attacker knows what he wants, he knows who works at the company, and he knows their name, too. Or it may be completely impersonal, and the hacker simply saw an email address he liked and wants to play with it.
8. Stolen and lost access badges—The easiest way to access a building is if you have an RFID pass. Criminals know that the badges that workers wear can get them unquestioned access to a building. And, as a bonus, the badges are easy to steal (people wear them dangling from their clothing and often even drop them on the street—this author has found at least three, potentially all-access badges on the streets of Chicago.) Badges can certainly contain a photo; but name, workplace, address, and so on, should be encoded in the chip. There should be a mail-to address on the card that *is not* the same as the location to which the card grants access.

Step 3: Remediate Issues

Number 4 is perhaps the most important item in the above list. Most penetrations that result in loss of data are socially engineered and will, at some stage, include some social element. Someone will receive an email with a link that will take the user to a spoofed Web page where the users will log in, thinking they are logging into their own systems.

Example

Mattie, an internal HR director, uses a custom-built payroll system that is built on top of a known technology. The password reset notifications sent out by the system *always look the same*. The hacker is aware of the system used. Perhaps he used to be an employee or a contractor. Perhaps he saw it on the software vendor's Web site and thought that Mattie's company was a client. He then culled Mattie's name from a published employee directory. Or maybe he worked out her email address by calling and asking questions about employment. It doesn't matter. He gets in by sending Mattie an email that appears to be from an internal email address. Its header has been forged. The email claims that multiple attempts have been made to log in using employee x's log-in, and she will need to reset their password. The email provides a link to the "system." Mattie follows the link, sees her internal log-in screen, and enters HER log-in information and is immediately redirected to her internal log-in screen. She blinks, and says to herself "That's odd, didn't I just log in?"

Mattie is pretty savvy; her company has a security training program. She immediately logs in and changes her password, and then reports the incident. The hacker had her log-in credentials momentarily, and if not for her quick thinking, he would have used it to successfully export the entire payroll, which he then would have held hostage or simply posted on the Internet.

How do you stop this sort of thing from happening? Spam filters may be able to trap these emails, but what if it comes in on a personal account? Most people would just raise their eyebrows and say, "That's interesting," and chances are good they wouldn't follow it, but you can't count on it. One step would be to not give the outside world access to internal, sensitive systems. Then the redirect would fail, and even if the hacker traps the sign on, he has to breach the physical location. Another way to prevent it would be to ensure two-factor authentication.

There are loopholes in any external facing system. Wherever a human being interfaces with an electronic system, this is an avenue of ingress that can be exploited. A seemingly secure operation such as entering a password and checking a fob on a keychain or a text message on a cell phone to access a system has a weakness. There is a password that remains constant, which means it can be observed or logged, and there is a keychain or cell phone that can be stolen, cloned, or replaced. Additionally, many different types of accounts can be *linked* together now, and hackers can daisy chain enough information together from the different password hints provided by these accounts that they can successfully leapfrog right into secure areas.

Gaining access to one employee's twitter account could conceivably be the single breech a hacker needs to be able to gain access to all of corporate systems—especially if the victim has access to everything and passwords set to automatic on his laptop, has linked password recovery of corporate accounts to both personal and work email addresses, and is someone who plays an active part in the online community and has a high level of visibility.

Here are some security items that should be ensured in each zone. Later, this chapter will explain the specific vulnerabilities of each zone while describing how to collapse the zones to more manageable, securable corridors:

1. Examine the security policy *as it exists today.* Don't just document how it should be and tell everyone how

it should be. Rather, show them how it is and tell them what to stop doing. Better yet, *stop them.* Don't allow employees to use their work email addresses in any nonwork-related capacity. Don't let them use their personal email addresses on corporate systems.

2. Don't allow employees to use their personal email addresses as password recovery points for any work-related systems.
3. Office systems should never be accessed from personal laptops, which may be unsecured or may have lapsed antivirus. If circumstances necessitate this allowance, then provide licenses to antivirus and firewall technologies to employees for free. After all, they are accessing work systems and ostensibly performing work while at home from personal systems. If the corporation can't see the wisdom in providing security, then disallow it and take the productivity hit.
4. Enforce work-personal email uniqueness. Somebody1@website1.com should not be under the same user as somebody1@website2.com. For example, your work email and personal email address prefixes must be different.
5. Do use encrypted tunnels, AES 256 entire drive encryption, and secure messenger services for moving sensitive data.

Securing e-discovery data will be challenging, and there will be many hurdles to overcome. Human behavior—changing it—presents the greatest challenge. Infallible controls must be put into place to protect this data, as it will likely represent the most sensitive data in the organization. Successful information management will facilitate the identification and securing of relevant data. Relevancy will play a key part in this process. Take the approach that there is an existing compromise—that there is already someone in your network. Minimize risk of exposure as much as possible—they can't get what isn't there.

Identification

The EDRM model breaks identification into a separate phase of e-Discovery than information management. This was perhaps for ease and beautification of the EDRM diagram. It is important to note that, from a fountainhead perspective, information management most certainly belongs in this position on the EDRM diagram. However, from a physical management perspective, information management encompasses the entire spectrum of the EDRM life cycle, with each segment, along the way, underscored by an information management system. Securing e-discovery then becomes a matter of interfacing and connecting to disparate information management systems that are designed to perform different tasks, or it becomes a matter of absorbing those systems into the collective corporate information system.

For very large or highly litigated corporations faced with a new lawsuit every day, it is not a matter of whether or not they will save money by bringing e-discovery internally, it is a matter of *how much*. By doing this, by bringing the identification systems in-house, corporations can then create a security cordon that contains the team infrastructure, the software used to identify relevant data, and the access and permission controls to the identification system, which should tie directly to its users. Typically, this would be the internal legal department. This cordoned system can then act as a launch pad for secure transmission corridors to vendors for further data processing.

For many corporations, and many IT experts, however, the term *legal hold* means very little. From a high level, very few corporations will be faced with litigation on a daily basis. There are several reasons for this:

1. They aren't big enough to make it worthwhile.
2. They are very transparent in what they do already.
3. They don't think that anything they are doing could ever cause a lawsuit to be filed.
4. They never thought they would ever need to sue another company.
5. The corporation is able to quickly settle any matters that do arise.
6. It's a shell corporation, and the owners are untraceable.
7. Economically, the corporation would collapse after just one discovery motion, so they declare bankruptcy and fold.
8. They haven't made anyone angry yet.

Generally, companies such as these don't concern themselves with e-discovery. However, some of them should. Item 3 above, in particular, causes many companies to be caught unawares. Some people simply don't realize that copying someone else's product is illegal, and they will even brag about it to complete strangers. These people are heading the wrong way down a one-way track. Any organization with revenues in the millions of dollars is very likely doing something on a scale that someone will notice, take offense to it, and file a suit.

NOTE: The Sedona Conference is an organization comprised of leading judges and attorneys who provide guidelines and frameworks for the proper conduct of legal hold, as well as other e-discovery activities.

When faced with a litigation hold requirement, business stakeholders should inform their technologists of as many details of the lawsuit as possible. Key stakeholders in a legal action are:

- Officers of the corporation
- In-House Counsel or other representation
- IT directors
- Managers of custodians

Each of these people should understand what makes a potential lawsuit. This will better enable both the attorneys and the information technologist to work together to produce the relevant documents.[3] What makes a potential lawsuit? Let's take a look[4]:

1. Something happens that causes loss of income, life, or injuries.
2. The corporation or person knew the potentially dangerous condition existed and had a legal duty to safeguard the damaged party.
3. The corporation did nothing, and was not in the process of remedying it, and prevention would have been the normal practice of a "reasonably prudent party."

Many types of lawsuits fit this scenario. One example[5] would be of a school that runs its own bus service and, every year, offers safety training to its Kindergarten children on the third day of school. Because it occurs at the end of the day on the third day of school, it means the children have *already* ridden the bus five times, with no safety training. At the same time, prevailing practices among similar schools require safety training before using the bus.

NOTE: Optionally, what can make a lawsuit even stronger is if the corporation tried to hide what happened. Best case scenario (for the plaintiff, not the defendant!) would be a case where the plaintiff is awarded punitive damages due to intentional misconduct. The author includes this information in part because it is interesting, and in part as a warning. Punitive damages may involve multiplying monetary damages, such as a tripling of the award.

One year, an incident occurs on the first day of school where an older child convinces one of the Kindergarteners that he needs to exit the bus at the next stop through the rear exit door, while the bus is moving. He attempts to do it but is stopped by the bus driver. The parent of the child writes an angry letter to the school and advises them that they should be providing safety training *before* the Kindergarteners are ever allowed on the bus. The school fears a lawsuit (even though no loss occurred), and the parent is put on an internal watch-list as "litigious."

The school then thanks the parent for the letter but does nothing. The school fails to actually respond to the threat. This is because the school administrators didn't understand the above rules. Now, this incident is inactionable because there was no loss to society. However, a year passes by and on the first day of school the incident recurs, with the same older child, and this time it leads to the injury of a Kindergarten child and a lawsuit is filed. The parent of the child in the first incident informs the parent of the child in the second incident, and even provides him with a copy of the email he had sent. The email letter becomes the centerpiece in the lawsuit, but the school denies that the email was ever sent.

The plaintiffs are granted access to the school, and over a single weekend they create exact duplicate copies of every PC and server in the district. The judge in the case is convinced that the school network, in its entirety, was instrumental in the incident—and FRCP 37 covers this. Whether or not criminal charges will be filed remains on the table.

Unbeknownst to the defendants, the judge e issues a civil search warrant, one that allows civilian experts—employed by the plaintiffs—to access the site and make forensic copies of all digital media located on the premises. This *includes* any thumb drives that employees may happen to be carrying on their person! To ensure that this civil search warrant was carried out, arrival on site was heralded by 20 black SUVs—a squad of fully armored and m16 carrying federal U.S. marshals—that pulled up into the school parking lot at 3 PM on a Friday afternoon when school was being let out. The school computer system administrator is located and ordered by federal marshals to relinquish complete and total access, passwords, tokens, and so on. Now enter the e-discovery and forensic experts who will take the school's information systems apart, piece by piece, and make forensic copies of every hard drive. They will render the entire school's information system as subject to discovery.[6] Upon inspection of the systems, the experts located a deleted copy of the email and dozens of other complaints about the school safety system

3. This is not to be interpreted as legal advice, but is based on the courtroom and work life experiences of the author, working and testifying within the federal and state judiciaries of the United States and with litigating attorneys for over a dozen years.

4. It follows, then, that a deeper understanding of the entire motivation and rationale behind these lawsuits will enable a system security architect to better anticipate and understand the nature of what is happening, and what is about to happen, to him. Or rather, what is about to happen to his security model. The following examples very closely parallel several of the lawsuits within which this author has served as an expert witness. For exemplification and clarity, certain aspects of the cases, including the overall nature of each, have been changed. Where applicable, references to actual cases have been included for further study.

5. This and any other stories, unless referencing actual cases, are completely fictionalized accounts. Names, situations, and places have been changed

6. *Covad v. Revonet*—Mag. Judge Facciola, in a landmark decision, reduced Revonet's arguments to dust when he ordered that the entire network was relevant to the action and ordered them to allow a team of COVAD forensic experts to enter the Revonet Sioux Falls location and create exact, forensic copies of all PCs, laptops, and servers. Over 125 forensic images were created at a cost of many thousands of dollars. Ultimately, Revonet declared bankruptcy. Revonet failed to provide a believable and reliable basis for determining that only particular subsidiary databases contained relevant documents, thereby rendering the entire networked database, and this included all PCs, subject to the other party's expert forensic handling and searching for relevant documents. United States District Court for the District of Columbia, Civil Action 06-1892-CKK-JMF, Document 95, Filed 05/27/2009.

in general, all of which created sensational drama in front of the jury, and resulted in a judgment against the district of many millions of dollars.[7]

This situation plays out in courtrooms around the world on a daily basis.Companies are simply aggregations of humans trying to make money. Sometimes they engage in activities that are unsafe or illegal in an effort to save money (or make money). Sometimes these activities are activities that put others at risk.

A less distressing, and also fictional, example would be the case of *HappyFlyers v. MadFlyers.* MadFlyers is a small company that manufactures model, remote control helicopters. Unfortunately, their engineer retired (he wasn't very good anyway), sales are slipping, and everyone is buying the competition's (Happy Flyers) helicopters, even though they are more expensive. MadFlyers CEO Gerardo Gutierrez purchases one of the Happy Flyers choppers and says, "What the heck!" and sends it off to his chop shop in China where they reverse engineer it and make a near exact replica. MadFlyers then sells thousands of the helicopters for half the price. Unbeknownst to Gerardo, the CEO of Happy Flyers heard about this, visited one of his shops, and purchased one of the knock-off choppers. Additionally, Gerardo isn't the only one who copied the helicopter. Six other manufacturers also felt the heat and similarly copied patented sections of Happy Flyers copter. Also unbeknownst to Gerardo is the fact that he has crossed paths with a patent house. Basically, Happy Flyers is a shell company, owned by a holding corporation that owns and protects many patents. The only actual work it does is to search the marketplace for potential violations of the patents it owns, new patents to purchase, and file lawsuits when violations are found.

Gerardo finds himself subpoenaed, and he is asked to settle for an undisclosed amount. Of the seven companies that were targeted in this patent infringement suit, MadFlyers refuses to admit what they did. They claim they sold "only five or six" of the helicopters. They also claim that they are working to pull and find all the invoices from their system, but they are having trouble accessing it. Again and again, Gerardo claims the system is difficult to access and that reports can't be run, that he has to go to the warehouse and do them one at a time, and so on. Ultimately, the judge allows an independent and neutral forensic examiner, escorted by federal marshalls, to enter the Mad Flyers warehouse facility in California, where several servers and PCs are imaged.

Subsequently, in court, the expert testimony reveals that he uncovered nearly a million dollars worth of sales of the phony copter, and that the sales were recovered from the database as orphan line item records, meaning that the original order had been deleted, but because someone had gone into the backend of the sales/order system to do it, and had done it incorrectly, the detail of each order remained behind while, from the front end, it would most likely appear that the sales never existed. The judge orders both parties to retire to a conference room and settle this matter, and he warns the defendant that *he will not like* the judgment that will be handed out should be fail to come back into the courtroom without a settlement. They settle for an undisclosed amount.

Identification, then, becomes a matter of asking a number of questions. First, one must understand what is happening to him or her in a lawsuit, and the degree to which uncooperativeness will aggravate the situation, and make the judge angry. Angry federal judges are not fun people. Don't make them angry. To facilitate the litigation hold process, many companies use legal hold software to manage the custodians and administer legal holds. A typical legal hold product will allow the legal hold administrator to perform the following identifications, and then inform the owners of the data, the *custodians*, to *hold* any and all relevant data to the matter. One piece of software, titled "Method," offers the following capabilities, which guide the hold administrator to input the correct information:

1. It will initiate the process of identifying *who are the custodians*—the people who have the data that is material or relevant[8] to the lawsuit.
2. Where is the data?
3. Are there backups, are there thumb drives floating around, etc.
4. It will provide instructions for next actions.

The role of a security architect, a system administrator, a CIO, a CTO, a technology director, and the like, goes beyond simple security and encompasses a holistic security model and a level of awareness that demands attention to the facts at hand. This means that, in the

7. Remember, this entire account is a fictionalized amalgamation of many cases and experiences of the author.

8. Two words that are often confused with one another are *material* and *relevant*. Here is an example of this confusion: Elaine alleges that she remembers witnessing a certain event at a certain time and what she was wearing because it rained on Tuesday. Elaine, while walking outside on Tuesday, got soaking wet. She preserved her dress in order to prove that it rained on Tuesday. The dress is material in that it will be offered to prove a specific issue in the case. Elaine's testimony would then be relevant, as she will testify that she wore the dress on Tuesday, and it became wet because it rained. Relevancy tends to tie together one or more material facts. For example, testimony to prove that the dress is a dress, or that the dress is wet, would not be relevant. However, any information pertaining to the purchase of the dress, the type of dress, documentation about how wet it was, and so on might be deemed as being *responsive* to the matter, which means the documents are eligible for evaluation in the process of admitting evidence, and means they are "discoverable."

model laid out in Figure 35.1, the interfaces of each zone must be identified and assessed. Mechanisms must be in place to deal with the movement of data, and the administrator must be equipped with a responsible, responsive plan that he or she can engage when litigation becomes apparently imminent. The EDRM model may take different shapes and forms in differing types of litigation, and reflect that no two IT infrastructures are built in the same way. In fact, we expect to see vast variations just within one information management system.

This chapter seeks to impart an understanding of the EDRM as it relates to information security. To do this, it underpins the structure of a lawsuit with the structure of a zoned security model, which will also vary substantially from one organization to the next and even from one lawsuit to the next. The point of this chapter is to provide an acceptable, sufficiently adaptable model whereby the flows of information between zones, and the type of information in motion, may be fully understood and modeled. By also demonstrating how risk can be mitigated by adjusting the activities, the reader of this chapter should begin to understand how malleable this model is and how the various decisions made to hire vendors, purchase licenses for internal use, and hire internal or external counsel can have a deep impact on the overall security model.

Identification Integration

From a security standpoint, then, how do we plan? By securing information identified as relevant internally, and by developing policies and procedures that govern how information is retained, we can then respond quickly and accurately to any demand for disclosure. In addition, we can do it while minimizing the risk of exposing the data in a vulnerable environment, or unintentionally releasing data. A corporation can then prevent unauthorized delivery of sensitive personal and corporate information into the hands of strangers. This section is titled Identification Integration because it will discuss how to integrate an identification system into the information management segment of the EDRM. Ultimately, it is most secure for all zones to be collapsed into this segment, because this is where the corporation can maintain the most complete control over the security of its information.

When the identification process is executed internally, as in Figure 35.3, observe how the entirety of Zone 2 becomes encapsulated by Zone 1. Zone 3 then collapses into a simple, manageable form, leaving us with a fathomable disconnect between Zone 2 and Zone 4. Zone 3 can then be treated as a secured conduit. Often, however, companies have no internal resources to which to turn when faced with electronic discovery requests. E-discovery is a relatively new field that experienced a surge of growth and acceptance in December 2006 with the new Federal Rules of Civil Procedure, which finally formalized the consideration of electronic evidence and codified it into law. Since 2006, hundreds of companies that specialize in electronic discovery (e-discovery) management have sprung into existence. Many of these companies possess vast experience in the field, but some of them are simply companies that once specialized in paper discovery and have now scrambled to hire anyone who has even a modicum of knowledge of the process so that

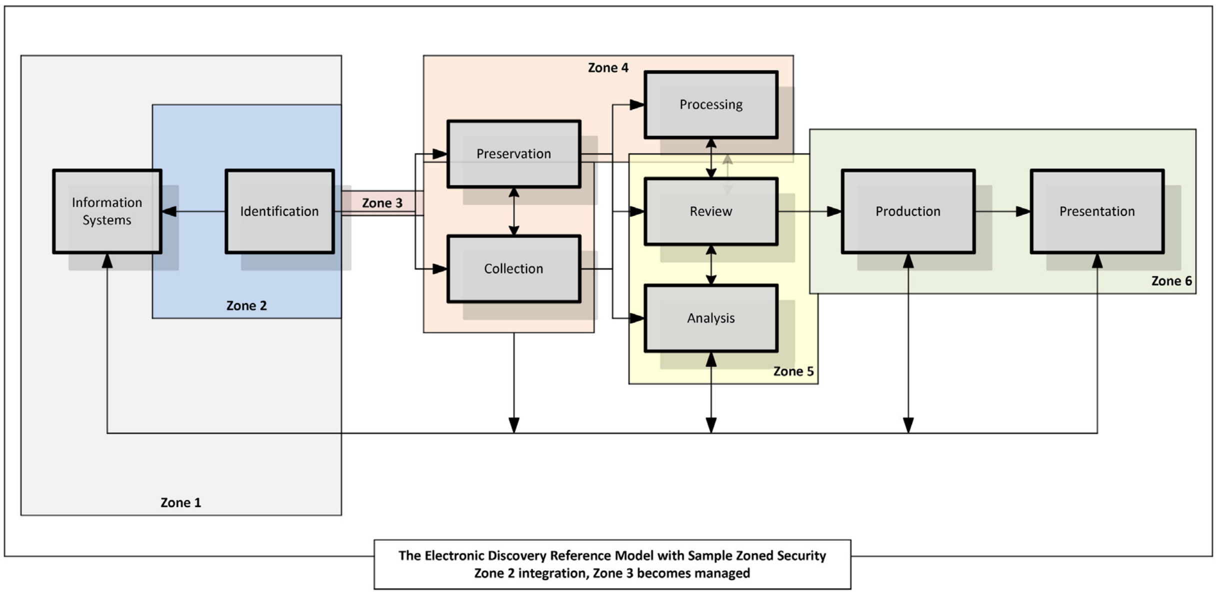

FIGURE 35.3 Collapsing Zone 2.

they don't collapse along with the paper industry. They have populated their staff with "experts" who have insufficient skills in searching and culling techniques, and lack significant expertise in deploying infrastructure to support the big data lawsuits of this decade.

Such companies are not easily identified—they possess all the tools and all of the staff, and they may even host very large cases for big-name clients. However, software vendors that publish effective software solutions do exist, and they may have some sort of "Best of Breed" programs. In these programs, clients are tested by the vendor to ensure that they possess the capability to successfully manage the program. Vendors will list these best of breed companies on their Web sites in special areas. The best software vendors will participate in programs such as Gartner's Magic Quadrant study. Every year, Gartner publishes a study of the competing players in almost all the major technology markets. A firm grasp of the principles put forth in this chapter will provide the background needed to build out a successful, and defensible, corporate EDRM implementation.

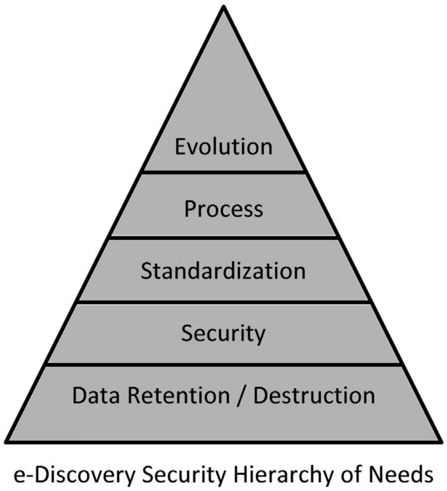

FIGURE 35.4 Getting it right. Not unlike Maslow's (see Figure 35.4) hierarchy of needs, enterprises need to focus on the most important tasks first—start at the bottom of the triangle and work toward the top. It makes no sense to be worrying about the nuances of converting .eml files to XML for more efficient storage if you don't even know where all of your backup tapes are going, or if your backups are even completing successfully.

Securing Zone 1

Zone 2 in this model is now subsumed by Zone 1. This is not to say that the information in Zone 2 inherits the permissions of Zone 1. It still maintains its own rules, but now it can do so using the same framework of information security that secures Zone 1. Security managers of Zone 1 may now also manage items in Zone 2 because they have internalized the function of identification. Perhaps they have hired internal counsel and installed an appliance that allows them to capture and cull information that is deemed relevant. Perhaps the identification process was as simple as walking over to Joe's desk, pulling the plug on his PC, taking it to a secure area, and bagging and tagging it. Always, when securing a computer that may be a pivotal item in a court case, standard, forensically sound procedures should be used to secure it. Any further reads and writes to the drive will be deemed as suspicious. Chapter 33 in this book, on cyber forensics, provides much greater detail on the procedures that should be used here.

Zone 2 notwithstanding, Zone 1 must then adopt some new standards of data security. In terms of defensibility, data must be preserved in such a way that is customary and necessary for continued business operation. It makes no sense for some companies to retain seven years worth of email. For some companies, however, this may be necessary. Zone 1, the information management phase, encompasses all that a business must do to simply operate, securely, day to day. When developing a model of security that incorporates electronic discovery, consider that there is a new model of need. Consider that businesses have a similar hierarchy of needs as Maslow's.

Each layer of the triangle describes the phase of development. The items at the bottom of the triangle *must* be executed effectively before implementing process. Process that you implement on top of a fragmented or an incomplete backup and retention strategy will be forced to change or adapt later on, and change is costly. Failure in this may also have deadly business consequences. Losing all of your responsive data in a lawsuit could be a business-ending event:

- **Evolution**—finding better ways to improve what you are doing. Be faster, better, stronger. Do more in-house, and do it more efficiently.
- **Process—**defining and understanding your information flow.
- **Standardization—**things like making sure everyone uses the same software, stores information in the same places, and uses approved technology for information transmittals. Ensuring that the policies carried out on the bottom rung are understood, make sense, and adhere to business best practices.
- **Security—**ensuring that you know your data isn't walking out your front (or back) door.
- **Data Retention/destruction**—ensuring that you are keeping what you want to keep, destroying what you don't want, and backing up data at risk.

Starting at the bottom and working up the pyramid provide architects with a scalable model of data security.

Alternatively, starting at the top and working to the bottom is similar to folding one's clothes before washing them. It makes little sense.

Securing Zone 2

Securing Zone 2, once it has been collapsed into Zone 1, then becomes a matter of definition. The breadth and scope of the discovery, the manner in which potentially relevant information will be identified, all scream for a comprehensive plan. This plan should detail the steps needed to identify the following items of information:

1. Custodians.
2. Keywords or time periods of relevancy. Discerning this may be a matter of conducting interviews and documenting the location of data.
3. Do backups exist? What format?
4. Is all information accessible? Inaccessible information, or data that has been destroyed *after it became apparent that litigation was likely* will present special challenges. It is important that all IT personnel understand that tampering with evidence may have very dire consequences.

This phase is about identification. As it relates to security, the following items should be of interest and should be secured from distribution:

1. Strategy plan—All items should be marked with the words "Confidential" and "Attorneys' Eyes Only."
2. Create an Identification Team roster.
3. Plans and spreadsheets that detail source lists should be stored securely. Applications that can track media should be created.
4. Access to software used to initiate a legal hold should be password protected, and only team members, trained in its use, should access it.

All information pertaining to litigation should be treated with the same amount of security with which one would handle sensitive financial data, if not more so. In the end, emails collected may contain data relating to *all* aspects of the enterprise—from logistical data to personal messages sent by the CEO to his administrative assistant—there could truly be very sensitive data released to the opposition. And, in the event of a "no-holds-barred" judgment? All data could go to the opposition—all of it. When it comes to the deeply probative nature of a lawsuit, there can be no doubt that, at some point, information from many sources may be culled. Here are some helpful tips.

- Build a solid identification system from the start. This will allow system administrators to respond rapidly and securely, with only responsive data.
- Create a solid, but not overly restrictive, communication system that raises corporate awareness. Inform corporate system users that the corporate system should not be used for personal communication.
- See to it that employees shred and destroy any personal emails they have sent.
- 'For employees' personal communication, make sure they use their own personal devices. In today's highly equipped society, there is no reason to use the corporate system for anything personal.
- Make it Group Policy at the corporatewide level to delete temporary Internet files upon exiting the application.
- Consider that some inter-relay chat messaging systems can be configured to save and send missed chats as emails, and create a policy that covers how these chat logs should be treated.
- Be aware of "cloud" data—data that a corporation may have created and is potentially relevant, but could be stored in a third-party SAAS system. Is this data easily exported? Can it be accessed and exported with custom queries?

Keeping personal communication off the enterprise system has several benefits. Aside from the inherent security benefit (users may launch harmful attachments from personal emails that are not scanned by the corporate email system), consider that with a Security Awareness Program:

- The amount of potentially discoverable data will be reduced.
- The potential exposure to harmful and misleading personal conversations diminishes or disappears.
- The program itself raises awareness that users should not write any emails that they wouldn't want to be made publicly available.

A strong security policy will allow the legal hold team to perform their work within a predefined and secure framework. An "anything goes" policy, while seemingly very employee friendly, can have disastrous results: When the professional, corporate system commingles with employees' personal lives, the amount of data increases, and the opportunities for email from disgruntled employees who have their own interpretations that they may willingly be sharing with those outside the organization, on the corporate system, increase. Keeping to the hierarchy and defining this stage of the EDRM within the corporation is key to securing this zone. Creating a responsive and secure information identification program *within* the information management system is essential to maintaining the utmost security of corporate data. When Zone 2 is subsumed by Zone 1, a secure conduit can be opened for the movement of data and for the subsequent integration of all zones into a secure work flow. The

alternative to assimilation of Zone 2 by Zone 1 is that outside consultants be granted unfettered access to entire systems, and that it be secure.

Many possible vendor arrangements can be made when dealing with the identification of data. Ultimately, whichever configuration is arrived at must meet several rules of e-discovery security[9]:

1. Information must always be encrypted when transmitted over the Internet.
2. Data cannot be lost: Create multiple backups and have a DR site as well. In the end, there is no such thing as a real "backup" of electronic data. There are only redundant points of failure.
3. Data can only be accessed by authorized personnel.
4. Data has not been changed or altered maliciously, which can be verified independently. This verification can be accomplished rather easily using methods that are well known in the e-discovery industry. An e-discovery vendor's sales team may not be up to speed on this, but their technical staff should know all about it.
5. Stored or archived data is encrypted. Data stored outside your system should reside on encrypted systems. A bankruptcy of the firm or vendor hosting your e-discovery data could mean that your data resides on systems that will be sold at auction.
6. Data can easily be located and destroyed when no longer needed.

Once these rules are understood, we are ready to delve deeper into the EDRM life cycle, and discuss the transition of data from Zone 2 to Zone 3 in Preservation, Collection, and Processing. Zone 3, then, becomes a securable conduit with easily established secure data transfer protocols, and security experts can shift their focus to battening down Zone 4.

Securing Zone 4: Preservation, Collection, and Processing

In the EDRM, preservation refers primarily to the act of requesting that all custodians cease and desist any and all deletion activities and any automatic deletion procedures respecting potentially responsive data. Effectively, though, the end result of the act of preservation, collection and processing, is that data is preserved. Until data has actually been collected, logged, and securely stored, it has not been preserved in the traditional sense of the word.

9. These items are derived from the Health Insurance Portability and Accountability Act (HIPAA; Pub.L. 104-191, 110 Stat. 1936, enacted August 21, 1996), which is not specific to e-discovery. In the end, it is up to organizations to make certain that they have complied with whatever standards are applicable in their industry.

Preservation

Typically, at the outset of litigation, or when litigation is reasonably likely, a requirement called a "legal hold" or "litigation hold" will apply. In a sense, this is the order that triggers identification. Some organizations should have the ability to immediately pull the requested data; for others, however, the criticality of collection matters very little. Once data has been identified, it then must be preserved in a forensic manner. This necessitates a discussion on metadata. You can't preserve and secure data if you don't know what the data is, where it is, or what data is necessary to be captured. Often, at the heart of this debate lies a conversation about *metadata* and about data *forensics*.

What is Metadata?

Metadata is data about data. For example, this chapter includes the following metadata, which can be derived using programs such as EnCase or FTK, which are forensic analysis tools:

As can be seen in Table 35.1, this metadata includes operating system (OS) information such as file created, modified, accessed, and last written. These timestamps may be very important because they will provide timeline

TABLE 35.1 A Listing of some of the OS Metadata that can be Derived from EnCase.

data when investigating some sort of breech. One such example would be an employee accessing documents during her tenure as an employee versus her accessing the file systems post-termination. Chapter 33 includes a description of these timestamps and what they mean. This metadata must be preserved. Other items that may fall into the category of "metadata" to be preserved include drafts, outlines, and all their subsequent markup, hidden text, track changes, and so on. As can be seen in Table 35.2, a much more extensive list can be produced using a software tool to extract and compile the data into a structure format.

TABLE 35.2 This Table Lists all of the Metadata that can be Extracted from a Document. This Extraction was Performed using a Tool called Relativity Processing.[10]

Ultimately, these tables demonstrate that a lot of data can be considered *metadata*. Whether or not they are, actually metadata is a philosophical argument. Regardless, a comprehensive policy can prevent the accumulation of this sort of data.

NOTE: Some companies set up all of their documents so that, upon sending through email, all sensitive track changes data are removed.

What is Data Forensics?

The word "forensic" means that the data meets or exceeds the standards required in a court of law for the information to be presented as evidence. Information, when properly preserved, must comply with several rules in order to be admissible. Not least among the rules is the need for proof that the information was not altered. There are two ways

that this can be accomplished. For civilian organizations, the preferred method is to hash the data and preserve the resulting hash. A hash is an algorithm that reads ALL the data on disk and creates a unique identifier. Nothing but a perfect copy of the data would result in the same hash. In other areas, the witness is enough. Ideally, the following scenario will provide sufficient proof of preservation to allow admissibility to court. Bear in mind, though, that exceptions abound. Just because one of these rules is broken doesn't mean that the evidence won't be admitted. Certain judges in any court, where the judge has the ultimate authority to decide law, may even allow a hard drive to be admitted that had neither chain of custody nor a hash that matched the original drive's hash.[11] Ultimately, it boils down to the judge's interpretation of the Rules of Evidence and how they may be applicable to electronic data:

1. The hard drive or files are acquired using a forensically proven method and hashed.
2. Paperwork that describes where the files were found and how the files were captured must be created and stored in a secure location with the images.
3. A witness must be available who can say that she personally collected the files and stored them.

These rules protect the electronically stored information from tampering or even accidental destruction. These rules must be followed during a collection activity. Collection is the actual practice of data forensics in motion. Remember, though, that data can become corrupt just sitting on a disk.

Collection

Collection is the logical successor to identification; in the EDRM diagram, preservation shows a double-sided arrow pointing between collection and preservation. Preservation applies first in the sense that the litigation hold requires that responsive data be preserved rather than deleted. Collection is an activity, and collected records are the result of that activity, and the collected records themselves must be preserved. Whether or not true preservation occurs is wholly dependent on whether or not the rules mentioned in the previous section were followed and whether or not the collection is properly conducted. Securing the data is entirely key to both. This creates a zone that cannot and should not be integrated with other zones. It should stand alone as an entity unto itself. A collection activity may manifest in several scenarios; each has unique security requirements:

- The electronically stored information (ESI) collected is stored internally.
- The ESI was collected by your staff from a remote location.
- The ESI is being collected from your location by opposing counsel's vendors.

Each of these scenarios requires special treatment. Security approaches will vary within each circumstance. There are many products that are used to do this work; they fall into several categories:

1. Boot device only
2. Network boot only
3. Network collection (this includes use of a crossover)
4. Direct or drive-to-drive acquisition.

Each of the above options will allow for two types of collections. Which one is needed depends on the case and on the type of litigation. If there is any possibility that locating a deleted file can alter the outcome of the case, then choose option 2, below, unilaterally:

1. Logical files
2. Physical disk image

Physical disk images present a very unique concern in the world of security. To a certain extent, a hard drive acts as a recording device. However, if there is a lot of churn on the PC, if many files are created and deleted, the files have the potential to multiply like rabbits. Imagine that the hard drive is like an onion slice, only with millions of concentric rings. If the hard drive is frequently defragmented, the layers of the onion build up over time. Often, what happens in the world of IT is that a user will "fill up" her hard drive. When this happens, the IT support technician, or perhaps the user, will clean up the computer by deleting files. Perhaps she will delete 50 gigabytes (GB) of data from accumulated logs, windows temp files, and email. That night, defragmentation runs, and all of the files that were on the outer ring of the drive are moved inward, filling the space where the deleted files previously existed, and leaving copies out on the outer edges. Windows delete *does not* overwrite the file. It only marks the space as free. The deleted file is easily recovered using a tool that can examine the master file table. To even the most incompetent of forensic examiners, there are now copies of her files that can very easily be located. And because she deleted so much data (perhaps a Windows log file had grown out of control at some point), it will be some time before the data reaches that outer ring and overwrites it. Defragmentation is good but must be followed by a secure wipe of the unallocated clusters.

Data Retention Policies

This leads us directly into data retention policies, which require that the security administrator understand the nature and location of any sensitive data, and ensure that

11. *US v. Gore.*

a sound and responsible policy be formulated around it. It dovetails into collection because, ultimately, the data that exists may be data that gets collected. A rigorous data retention policy will prevent the exposure of outdated and irrelevant files.

Deleted files are a security concern because they may still be extant. The following items present deleted data security challenges:

1. Email databases.
2. SQL log files. Often, SQL log files are not properly maintained. See the sidebar: "Managing SQL Server Log Files" for directions on how to keep the logs in such a way that they will remain efficient and continually overwrite themselves. It is not uncommon to find an unmaintained log that contains 150 GB of past transactions. Left to its own devices, SQL will allow a log file to grow interminably, or until disk space runs out.
3. Decommissioned servers.
4. Old backup tapes.
5. Forgotten share locations. The author of this chapter once located one year of database versions. The database was central to the case.
6. Internet Explorer cache files. This is the backstage pass to a full-blown, no-holds-barred collection order by the judge. Internet cache files, unless regularly cleaned, will grow to be quite large and will contain a recorded history of user activity. Many companies use online tools for contact management. The Internet history, then, may contain a record going back several years of every contact created in the system.
7. Local drives. Users like to save files where they know they can find them. Most users have been bitten by IT enough times to want to make certain that they keep their most important files on a local drive.
8. Shadow copies, versioning.
9. Partial files in file slack. When a file writes to a windows cluster, it takes the whole cluster. You can't store two files in one extant. However, if one file takes up an entire sector and then just one byte of the next sector, if another file (deleted) lived in that next sector, it would be recoverable. It is difficult to recover these files, but in the normal course of an examination of a PC, a forensic investigator will stumble across many items of interest. Due to deletion activity and defragmentation, there may exist many, many copies of a single file. When that file gets deleted, and partially overwritten, it may still exist in dozens, if not hundreds, of other places.
10. Decommissioned laptops and PCs.
11. Hard drive upgrades. Stacks of hard drives, regardless of being slated for destruction, become discoverable when a legal hold is issued.
12. PDAs, tablets.
13. Digital cameras.
14. Smart media cards.
15. CDs, DVDs, USB thumb drives, digital audio and video tapes, voice mail, and surveillance servers.

There are many enterprise software packages available that handle secure deletion. Secure deletion means at least one complete overwriting of the data. Some organizations operate at a heightened level of anxiety and may require as many as 35 overwrites of the data. Gutmann theorized that 35 overwrites of data are required to fully obliterate the data from the surface of the drive. In terms of meeting modern security requirements, this is probably excessive. The Gutmann algorithm, devised by Peter Gutmann and Colin Plumb, was targeting certain types of drives, of a certain track density, and so they suggested that near perfect obliteration of any residual magnetic data could be accomplished by writing a series of 35 patterns over the disk regions being deleted. The patterns are designed specifically for three different types of drive data encoding techniques that were prevalent in the 1980s.[12]

Sidebar: Managing SQL Log Files

- Ensure that log file backups are set to run at least once every hour. Consider running them more often in the following scenarios:
- You want to recover with less than one hour of data loss.
- More data can be written to the log file in one hour than is desirable.
- The amount of data written to the log file in one hour causes the log file to fill up the drive. SQL marks the log file as reusable once it is backed up, so it shouldn't grow too large.

Note: Some single transactions in processing software are quite large and may result in log file growth through multiple transaction log backups. This can prevent successful log backups.

- Ensure that the growth of the log files is set to at least 512 MB.
- In certain situations, many gigabytes of data may pour into a log file before the next scheduled log backup marks space as available. Unanticipated growth can also occur when extremely large transactions run. Should this occur, use some sort of log file size monitoring tool to control the size.
- When necessary, grow the log file size in anticipation of any large influx of new data.

12. Secure Deletion of Data from Magnetic and Solid-State Memory, Peter Gutmann, July 22–25, 1996, Sixth USENIX Security Symposium Proceedings, San Jose, CA. http://www.cs.auckland.ac.nz/~pgut001/pubs/secure_del.html.

To this date, no software or hardware product exists that can read the outer edges of a disk track and recompile overwritten data on a modern hard drive—unless, of course, one believes in a secret government facility that nobody knows exists that hosts an array of scanning probe microscopes (SPM), as well as scientists and analysts. Secure deletion, then, means at least one complete overwriting of the data and includes file slack (regions of sectors that are not being used by the file) and unallocated clusters. Doing it twice would be advisable; if there are two station points in the workflow, it will ensure at least some protection from human error.

Some organizations operate at a higher level of anxiety and may require as many as 35 overwrites of the data, using the Gutmann algorithm. The reason for this level of deletion was due perhaps to misunderstanding of the theory and a paper published by Peter Gutmann. In his paper, he described the potential to recover data from the outer edges of tracks using scanning probe microscopy, and the potential to recover overwritten data through a form of error-canceling read in which the calculated signal from the current data is subtracted from the signal that's actually read, with the difference being due to the influence of previously-written data.[13]

The procedure itself—the use of a robot-controlled drive mechanism and an oscilloscope to collect data from an 80-MB disk pack—has, in fact, been accomplished, and it was verified that the data did have the appearance of a true bit-stream that could then be further analyzed for comparative data.[14] This would be a very challenging operation, but it is conceivable that, if portions of the files are known, it could be extended to "decrypt" three or four passes at different locations in the same track. However, modern drives are far denser, and due to the use of advanced recording techniques, the potential for this sort of attack to be successful is extremely unlikely.[15]

Ultimately, there are software products that can perform truly secure deletion on modern drives with just one pass. Additionally, secure deletion should take place as part of the defragmentation routine. In any security-conscious enterprise, the secure wiping of the unallocated clusters should always happen *after* a defrag.

There are only two ways to destroy electronically stored data. You can overwrite the media, using software, or you can physically destroy the hard drive. SSDs present unique challenges as well.[16] For the physical-destruction option, any severe deformation, perforation, or incineration of the platters will suffice. Commercially available products such as diskstroyer have received good reviews as well.

The security of collection, then, is not just about the security of how the collected data is stored—this will be discussed in the next few sections. Rather, it begins with the security of the data itself that is being collected: You most know where data lives, and you must work to ensure that you know what data is being taken. It also means that the data must be stored in such a way as to take all possible and reasonable precautions to prevent data loss. Data loss, whenever it occurs, must be fully documented and explained, and it must not have occurred due to human error or willful neglect. This also means the data must be securable and identifiable.

The practice of collection can be divided into two categories: internal and external. Internal collection occurs when an organization looks inward and investigates itself using staff or consultant data forensic examiners. The motivation to perform the work stems from internal concerns, such as incidents involving earlier misconduct by a terminated employee, and there are internal stakeholders. An external collection occurs in litigation, where many parties may be involved.

Internal Collection

Many large corporations have their own internal forensic groups. However, even large corporations may turn to specialized forensic experts when unique circumstances arise. An internally conducted collection, though, will be one where staff employees, who are members of the enterprise domain, perform the work of securing, copying, and storing the discoverable information. A number of methods are employed:

1. Appliances are installed throughout the network.
2. Enterprise software allows administrators to capture everything from individual files to entire disk images, remotely, with two options:
   a. Systems are monitored for breaches in security policy and, when a breach is detected, the user system is locked down and the evidence is collected.
   b. Systems are not monitored, and collections are conducted only when suspicious behavior is observed or upon employee termination.
3. Physical collection—The drive is harvested, imaged, and stored, and then a standard disk image is redeployed to the machine.

In each of these methods, the end result is that a large amount of redundant data must be secured and preserved for, possibly, a very, very long time. Lawsuits can last many years, or regulatory compliance may require retention of up to a decade. It follows, then, that the location,

13. Email from Peter Gutmann to author, dated 10/5/2012.
14. Digital Archeology with Drive-Independent Data Recovery, Christopher Fenton, ELEN E9002 Research Project Final Report, Summer 2011. http://tinyurl.com/3jhe2os.
15. Email from Peter Gutmann to author, dated 10/5/2012.
16. http://www.cs.auckland.ac.nz/~pgut001/pubs/secure_del.html#recommendations.

nature (matter), and status of all data be tracked carefully. This data should be secured at a much higher level than other data in the enterprise as it is, most likely, a corporate espionage goldmine of all of the business's most sensitive data:

- Two-factor authentication
- Physical access with surveillance and biometric access controls
- AES 256-bit encryption where possible
- Hardware and data destruction policies
- Group-based access by matter

Often, internal forensic examiners provide advice and expertise in externally related matters, but often, depending on the matter at hand, these examiners will work tangentially with external consultants on projects that involve externally driven litigation.

External Collection

Often, when external adversarial forces are at play, enterprises choose to involve external collection experts. Ostensibly, this shift stabilizes liability and planning from internal sources, already taxed with managing internal risk, to an outside firm. These external firms should be experienced and should be able to easily integrate their tools to your systems for a speedy and accurate collection of data. They are often managed by in-house counsel in tandem with external counsel. In the rather small world of e-discovery vendors, the vendors selected by both sides will likely have worked together in the past. Interview any potential vendor carefully.

Occasionally, a court will allow, even at the protest of the opposing defense's argument, plaintiff's staff ESI specialists to conduct an on-site collection. It does happen—but it is not the normal course of events. A corporation that responds and complies with discovery requests in a timely fashion, demonstrating cooperation, will not face sanctions. Typically, by the time it comes to the "other side," being allowed to put their experts in the living room of an ex-employee or the data center of the opposition, things have become fairly combative in the courtroom. The reason for this is usually the utter failure of one side or the other to adhere to the bottom layer of the e-Discovery Security Hierarchy of Needs. This short list details some of the reasons why a judge may allow the opposition's experts full access to the other side's data center:

1. Failure to produce relevant documents on the agreed to timeline
2. Failure to produce relevant documents in the agreed upon format
3. Denial that any relevant documents exist
4. Failure to appear
5. Refusal to pay costs associated with discovery, or claims of financial destitution
6. Failure to provide a believable and reliable basis for determining whether something is or isn't relevant.

All of this exemplifies the need for a robust backup and data retention policy. Acceptable use policies are also a key part of this. Zone 3, as shown in Figure 35.3, becomes a matter of physical or encrypted tunnel transport of data. Often, the amount of data involved in a collection can approach many terabytes or petabytes in size. Movement of such large volumes of data, when it requires processing, becomes infeasible. Fortunately, with proper encryption, moving the data via hard drives, using accepted shipping methods, provides adequate security. Backups of data should be retained, and pass-phrases that allow access to the data should be transmitted securely. Should the need to transport dozens of drives via courier arise, ensure that the courier has a copy of the order on his person and in the hardened transport case, with the drives.

Collection "Don'ts"

Enterprises faced with litigation for the first time often make severe mistakes. A good example of a first-time litigation is where an employee storms out of the investors' Office of Alice Rabbit and Hole, and the next week begins working for a rival investment firm, Tweedle Dee and Dum. Suddenly, clients that were long-time, loyal customers are dropping their accounts with Alice and moving to...yes, the Tweedle, where the ex-employee now works. Later, the CEO of Alice receives a brochure, passed along from a client. It outlines a new pricing structure for the opposing firm's services that mirror the work being done at Alice, work that the ex-employee participated in developing. The brochure appears to be the exact same layout with only a few slight differences.

The CEO calls his IT director and demands an explanation. The IT director panics and saying "I'll get to the bottom of this!" immediately goes to access the ex-employee's laptop. She finds it on the workbench of an IT associate, halfway through a reload of the OS. She halts the work. Next, she browses the network to the ex-employee's share and begins to browse the directory contents, searching for content that the user shouldn't have had in her drive area—files that were thought to be restricted to marketing. She finds interesting files, and then she connects a hard drive to her network and copies all of Alice's files to the hard drive. Then, thinking to herself, "Gee, I could really use all that space she was hogging," she deletes all of the ex-employee's files from the network share.

Ultimately, Alice may still have a case—until, of course, a private investigator discovers that the

ex-employee and the IT director had had an affair. Ultimately, the case would have been far simpler and easier to execute had an intact laptop been available, a laptop that may have shown evidence of the ex-employee using Webmail to airlift files from the corporate network. Furthermore, a protocol in place to handle disgruntled employee departures would have been prudent. The CEO should have instructed his IT director to engage the protocol, which would have resulted in forensic quality images of everything the ex-employee had ever touched. Now, there will be a long-drawn-out legal battle that will be very costly, because Alice Rabbit and Hole have, essentially, a weakened position.

Processing

One might think that, once the data has been identified, properly collected, and shipped, the heavy lifting is completed. It is, in fact, only just beginning. The following searches may now need to be executed against a data set that is largely unstructured. Processing takes unstructured data and structures it so that future searches may be efficiently executed. Processing software provides, at a minimum, the following functionality:

- File types.
- While a collection may have targeted spreadsheets and documents, to be thorough the effort may have swept up files that are not the correct file type. Or the collection technologies used targeted areas such as unallocated clusters, compressed files, or entire file systems, and the types of files that were of interest didn't become apparent until later in the EDRM life cycle. The processing tool will recognize these files and will not process them.
- Date range culling.
- Database conversion.
- Files stored in databases, or information stored in databases, present unique challenges. A customer database that uses a Web interface to access the data may require a design team to re-create pages that display the information, which can then be reviewed, or they may simply be required to search the database. This requires that the database server be hosted by the processing agent.
- Keyword searches.
- Custodian organization.
- De-encrypting of encrypted files—the ability to enter in passwords or to "try" lists of passwords.
- It will remove National Institute of Science and Technology (NIST) items (De-NIST). Earlier, file hash values were discussed as being unique identifiers for a file that possesses a certain content. As passwords are broken, unusual compression algorithms unlocked, and hidden files uncovered, standard system and program files may be uncovered (this may be conducted multiple times, any step of the way).
- Deduplication Customized lists of hash values are created, and duplicates are removed. There are three ways to do this: globally, by custodian, and by family or child. When the context of the item does not matter, then global deduplication is best. If the context, such as the location of the file, who sent it, and its location, matters, then dedupe families only. Often, users will have local archives of files, which will contain large volumes of copies. A 5–6 TB corpus can easily be reduced through deNIST'ing and deduplication.

Ultimately, some combination of all of the above may be necessary as well. For example, after identifying that any email sent by an employee during a certain date range may be relevant, further analysis may be needed.

Securing the Processing Architecture—Zone 4

In Figure 35.3, Zone 4 encapsulates preservation, collection, and processing. Each of these items requires special treatment. In reality, preservation is a process that begins with identification, issuing a legal hold, and collecting the data; and data must be "processed" each step of the way. Data is not truly preserved until it has been securely copied, logged, and moved to a staging area where it can be accessed and reviewed at a high level for relevancy. In Figure 35.5, the upside-down triangle represents a funnel.

The EDRM is actually a drawn-out preservation and display process, and as we move through it, the amount of data being manipulated should shrink. However, sometimes things happen. For example, perhaps many compressed archives will be discovered, or deleted partitions recovered. There may be momentary bursts of data. Recall also that the entire process is cyclical. There may be many separate requests for disclosure in a single case. Storage and sizing become major challenges of

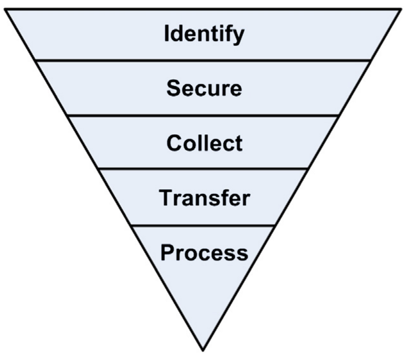

FIGURE 35.5 The preservation effort doesn't end with a simple backup and archive of the data. Throughout the EDRM cycle, the act of preserving metadata and file integrity remains important.

e-discovery architects, and securing the storage becomes a great challenge for security architects.

As storage bursts, emergency measures may need to be executed to meet deadlines. If emergency protocols do not exist, they cannot be executed. An example of an emergency protocol would be to have agreements with companies that sell storage and servers to execute on pre-authorized purchase orders within 24 hours. This is normal, and hardware vendors are prepared for such requests as they also tie into DR strategies.

In both planned and unplanned situations, servers will get moved, disk arrays transferred, and SAN fabrics re-architected. An adept security plan considers this contingency, is adaptable, and provides for extremely rapid scaling of the environment. This is not a "let's budget it for Q3" item. This is a "We need it, and we need it now, or we could get fined a million dollars" situation or, from the law firm or vendor perspective. "We need it, and we need it now, or we are going to lose an $85 m a year client." This sort of work occurs not only at small businesses across the world, but in the very largest enterprises that exist.

British Petroleum (BP) and the *Deepwater Horizon* case will, when all is said and done, very likely involve thousands of people and many terabytes of data, and will involve many millions, if not over a billion, in legal costs alone. Duplicative work can double and triple costs. Deficiencies in process can create even greater inefficiencies.

In 2007, this author was involved in managing the electronic data for a large class action suit that involved a consumer loss. Thousands of consumers had a home remodeling component that had failed due to manufacturing defects. The electronic discovery included thousands of joint photographic expert group (JPG) digital photographs. Nearly all of the photos were far larger than needed; a short experiment proved that the images could be reduced in size with no discernible loss of quality. Simply observing that 80 GB of images could be reduced in size to 10 GB can reduce storage costs by 8 times! Why is this important to security? Properly securing e-discovery includes ensuring manageability of the data. Data that booms in size rapidly begins to break down the barriers of security. Escalating costs cause corners to be cut and will leach funds away from the security budget. In the e-discovery industry, all-hands-on-deck emergencies are common, if not daily, events at many firms. Maintaining security should be the first priority. New servers introduced should be sanitized of any data, disjoined from other security groups, and should not have outbound Internet access.

The processing arena should be cordoned through DMZ technologies as described in Figure 35.6. Differing technologies have differing methods of access. At every step of the way, intrusion detection systems, intrusion prevention, and virus and malware detection systems should be dovetailed with each processing step. Figure 35.6 provides a sample configuration of how different servers may be tied to security cordons that are designed to minimize the risk of infected files being inadvertently viewed, which in turn can inadvertently execute malicious code. Staging areas, which are large disk repositories where data is stored as it is being accessed and manipulated, allow, tangentially, for other processes to be used to scan and monitor these areas.

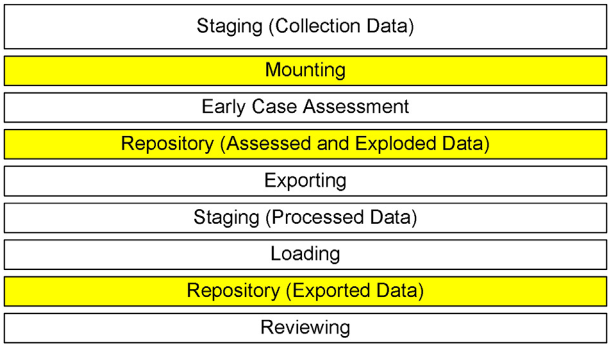

FIGURE 35.6 Each of the shaded areas represents either a static location or the process that creates the data that resides in that repository. Shaded areas indicate key areas where virus scanning activities may take place.

Staging (Collection Data)

Figure 35.6 introduced the concept of staging and the issue of having a secure staging area. In large litigation cases, collected files can arrive in many formats. Also, depending on the vendor, the work that remains to be done may differ. For the sake of simplicity, in this diagram, the assumption is that many forensic images of disks have arrived and have been stored on a high-capacity storage array.

Mounting

Subsequently, for processing, the forensic images are mounted as drive letters. At this time, performing a virus scan is not necessary. The files are read-only—if a virus was found, nothing could be done except to make note of it and exclude it, or mark it for manual review if it is a relevant file. In fact, depending on the method and software used to process the data, this is one of the options. However, at this stage, forensic tools are used to cull the data, and viruses that exist in system files may be ignored if they are in uninteresting locations. As part of culling, other processes may simply export all data from the mounted layer to a secondary staging area, and then may scan the entire area and quarantine infected files. Infected files may, of course, include files that are relevant.

A virus scanning utility that allows for cleansing of the infected files should be used.

Early Case Assessment (ECM)

During the assessment process, the risk of a user coming into contact with a virus increases. Decommissioned hard drives, unflushed quarantine directories, USB drives, thumb drives, spam email, and so on, can all rise to the surface. Especially, as the processing tool fails, one may come into direct contact with the file that failed, and the reason for the failure may be that the file is infected. As the ECA software service searches files, relevant files may be loaded into RAM by an unsuspecting user wishing to review a file. The file may be infected and may not appear in the viewer properly, so the user may choose to access the file and open it. When this happens, the virus is triggered, and a malicious hacker receives a notification on his bootleg cell phone that one of his viruses has been activated. Imagine his delight when, upon accessing the servers, he discovers that he has complete control over all of the electronic data of a highly sensitive litigation. Perhaps it is a merger. Perhaps it is a high-profile divorce, or bankruptcy, or product liability.

Additionally, technicians working with the files may erroneously believe that the processing software *failed* to process the file. They won't realize that the file is infected, and they may actually spread the virus by sending it to the software vendor. All files that are identified as suspect during processing should be quarantined and scanned before further evaluation.

Security around these areas cannot be tight enough. These systems should not have Internet access, and there should be double-layered, interwoven defenses of firewalls, intrusion detection, and intrusion prevention, even in disconnected systems. Some viruses are merely designed to infect other files and/or inflict damage. Once activated, nothing is to stop the virus from wreaking havoc on the servers. Ultimately, the infected files may have to be produced to the opposition in the lawsuit. Imagine how unhappy they will be if they discover that their entire network became infected by files in the production they received from opposing counsel. Referring back to Figure 35.2, outside of Zone 1, Zone 4 presents the greatest security challenges.

Processing

In this step of the EDRM, by now potentially relevant data has been identified. It may be a handful of files, or it may be millions of files. The current atmosphere of electronic discovery is one of "more is less" and so the discipline finds itself faced with issue of "Big Data." The end result of processing is that a "package" is created, or a series of them, that contain all of the natives and all of the metadata information, extracted from the natives. This includes something called "extracted text." Extracted text is nothing more than the body of language encapsulated in a file. For example, in this chapter, the extracted text would include all of the alphanumeric characters, with no formatting. It would also include any hidden comments, track changes, and any markup notes. This will all be stored as Unicode, so that special characters may be preserved and later searched. This package of data, which may actually be many terabytes, will then be transmitted to a new location. This new location may be internal to the corporation, to a law firm, or to a vendor data center. Review and analysis represents a major shift, or interface, where large amounts of data are likely to shift into a different area. That is, a copy of everything processed is now ready to be looked at and loaded into a hosted review tool.

Securing Zone 5: Hosting/Review

For some organizations, the hosted review may be integrated within the processing cordon. However, for many it is not, so this chapter treats it as though the data will be moving to a separate entity, either internal or external to the organization. Once the package has been received in the hosting review center, it must be loaded to the review software. Some software processing platforms may integrate directly with the review tool. For example, the software product Relativity includes a processing package—data may be pumped directly, SQL server to SQL server, from the processing center to the hosted review platform. Antivirus scans should continue, for two reasons. First, this system will very likely be connected to the Internet. Large-scale litigation requires many reviewers, and these many review shops are located all over the world. The enterprise data is about to go global. Second, virus definitions are frequently updated. A file that scanned "virus free" yesterday may not actually be virus free and may just be a time bomb, waiting to be set off.

More is Less

This returns us to the "more is less" philosophy prevalent in e-discovery culture in 2012. This philosophy is being countered by recent developments in automated review. In the sidebar "Relativity-Assisted Review," Constantine Pappas discusses assisted review, which is a way of programmatically eliminating documents from the potentially relevant population of documents. This sort of technology may often reduce the cost of analysis as well as the amount of data that needs to be reviewed by humans. If exposure is measured by surface area, then an increase in the volume of documents in e-discovery effectively increases that surface area. Primarily, this is because

additional computer systems will need to be set up (more Web servers for a hosted review) and because of an increase in human eyes that are performing the review. By leveraging predictive coding tools *before* releasing all of the data, exposure may be significantly reduced. The exposure here is the exposure of sensitive corporate data to hundreds of reviewers. Fewer reviewers means more security and less potential that someone will steal corporate data. It also means that, if the system is hacked, fewer files will escape. Exposure is not curtailed, but it is certainly reduced.

Software products that provide review services should be secure. They will have received "A" ratings from security auditing service companies. In response to security concerns, security consulting firms work diligently to ensure that proper security precautions are integrated into the platform for things such as:

- JavaScript injection
- Structured Query Language (SQL) injection
- Cross-site scripting
- At least AES 256 encryption of Web site and installers
- FIPS
- Signed
- Secure Session Cookies

Additionally, any security manager or software provider should be cognizant of new threats. Frequently, clients and peers, along with blogs and journals, are great sources of information. Keeping an eye out and seriously considering all threats or descriptions of potential threats, regardless of the source of information, can mean the difference between correcting a potential SQL injection vulnerability and having it remain to be discovered by a hacker.

Sidebar: Relativity-Assisted Review

Relativity-Assisted Review is a workflow process designed to save time and money during the electronic discovery phase of a lawsuit or investigation. The process captures human decisions on sample sets of documents and in turn applies those decisions to other documents in the same database that meets a predetermined conceptual similarity threshold. It is an iterative workflow, divided into phases called rounds. The number of rounds necessary to complete the project varies, depending on validation criteria and other case-specific variables.

The tool employs text analytics categorization, specifically an engine called Latent Semantic Indexing (LSI). First, the documents to be categorized are indexed; these analytics indexes typically filter out email header information and other repeated content that could otherwise serve to confound effective machine learning.

Once the index has been created, a sample set of documents is generated. A random statistical sample is very often employed, although it is also quite common to choose known documents that are believed to be excellent candidates for machine learning. Sampling by this latter method is called judgmental sampling.

Human reviewers will then apply values to a designation field (typically as either Responsive or Non-Responsive) for each sample document. Once all documents in the sample set have been reviewed, they are submitted for Categorization by the system. When Categorization is complete, the categorized documents are then sampled into new validation rounds, which human reviewers check for accuracy. Each instance in which a reviewer corrects the system is called an overturn, and the process of sampled validation review and Categorization is repeated until the overturn rate reaches an acceptable level or no longer changes. This effect is called stabilization and indicates completion of the Assisted Review phase of the discovery project.

Ultimately, the 'More is Less' process can greatly reduce the costs and time required to review a large number of records. This is accomplished by being able to isolate and either de-prioritize or disregard the Non-Responsive population, which is typically an overwhelming majority of most data sets. In addition, the tool amplifies human expertise, taking each coding decision and multiplying it many times over. This process greatly augments both consistency and decision-making transparency when compared with traditional linear review. Review tools, even Web-based ones, are most often secured in one of the following methods:

1. Simple forms security over HTTPS to a Web server.
2. Two-factor authentication with an integration of the application with something like RSA.
3. Portal-based access. One organization, Juniper, uses Uniform Resource Locator (URL)-rewriting to control access to Web-based applications, adding an additional layer of token-based authentication security to an already secure application.
4. Thin-client remote access. Remote desktop access uses something like Citrix to allow users server-next-door speeds when using the Web-based tool. It also prevents any information from being downloaded to the users' machines. This may assist with the compliance to some safe harbor rules and for overseas access and review of data. Some countries, such as UK, have very stringent policies on disclosure of motherland data to overseas entities.
5. Site-based security—Vendors own and control the review arenas, and the machines are locked down so that data cannot be loaded to a thumb drive. Users view documents in a basic dumb-terminal setup.

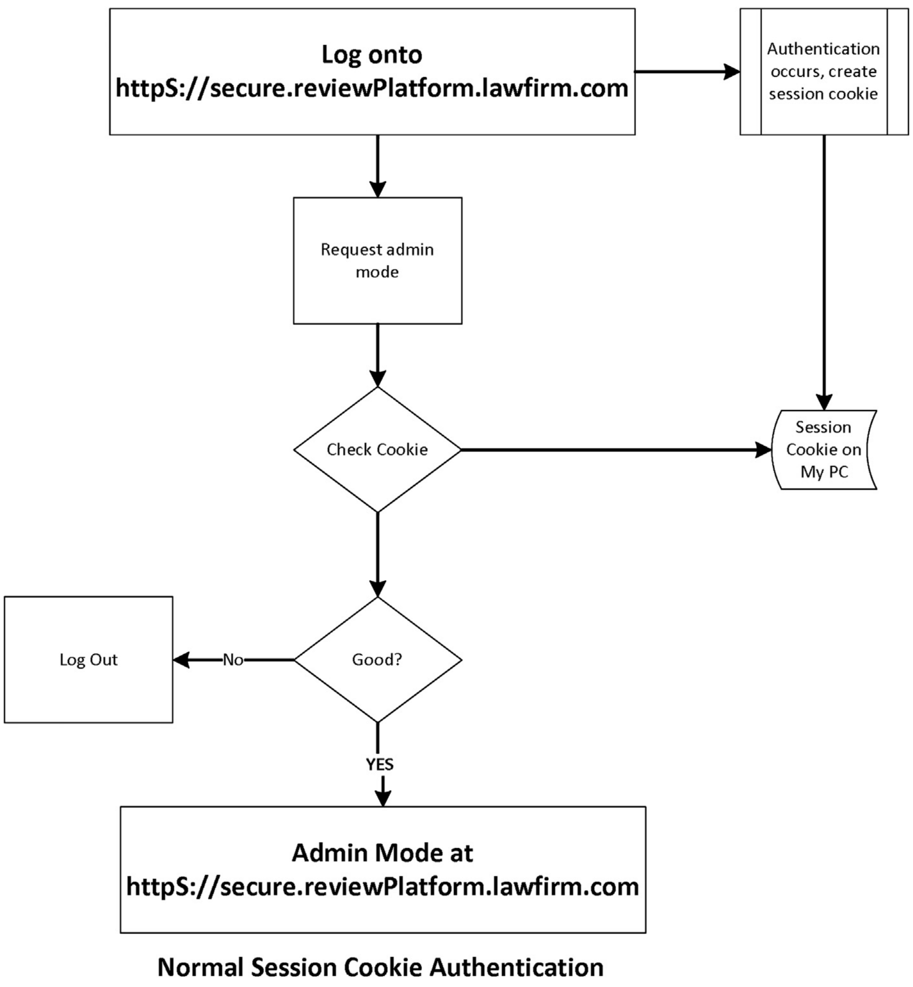

FIGURE 35.7 In a normal authentication, the cookie is generated by the browser and shared with the server. Subsequently, the browser is authenticated using the same cookie.

Consider the flowchart in Figures 35.7 and 35.8. In this flowchart, the ease with which an infiltrator can secure admin access is described. These electronic discovery systems contain, at times, extremely sensitive data.

Review and analysis are in the same vertical in the EDRM. Essentially, they are one and the same—analysis often takes place exclusively in the review platform. However, while there are many things that many review platforms can do, there are many things that they cannot. Not all review platforms can perform:

- Entity Relationship Mapping
- Voice recognition
- Threading
- Benford's Law
- Gap Analysis
- Deduplication
- Manage projects
- Bypass painful load file management
- Audio and visual search

Often, once documents have been coded by reviewers, data must be exported from the review platform and into some sort of analysis tool or another. This data may still be considered to be proprietary to the corporate entity and should remain under the same controls as any other data. A good review application will have permission-based security on various functions, such as the ability to download natives or to export data to Excel spreadsheets. Security will consider that many different software products will have special requirements and require varying levels of security permissions on the network.

Review platforms also must have storage capacity, and the same storage capacity issues can occur here that come up in processing. Additionally, there are, in fact, virus threats even at this stage, where one would think that everything had already been scanned three or four times.

Consider the zeroth day threat, where a threat is considered to be occurring on the "zeroth" day when, as of yet, it has not been discovered. It is true that files that are in the repository of a review platform have most likely

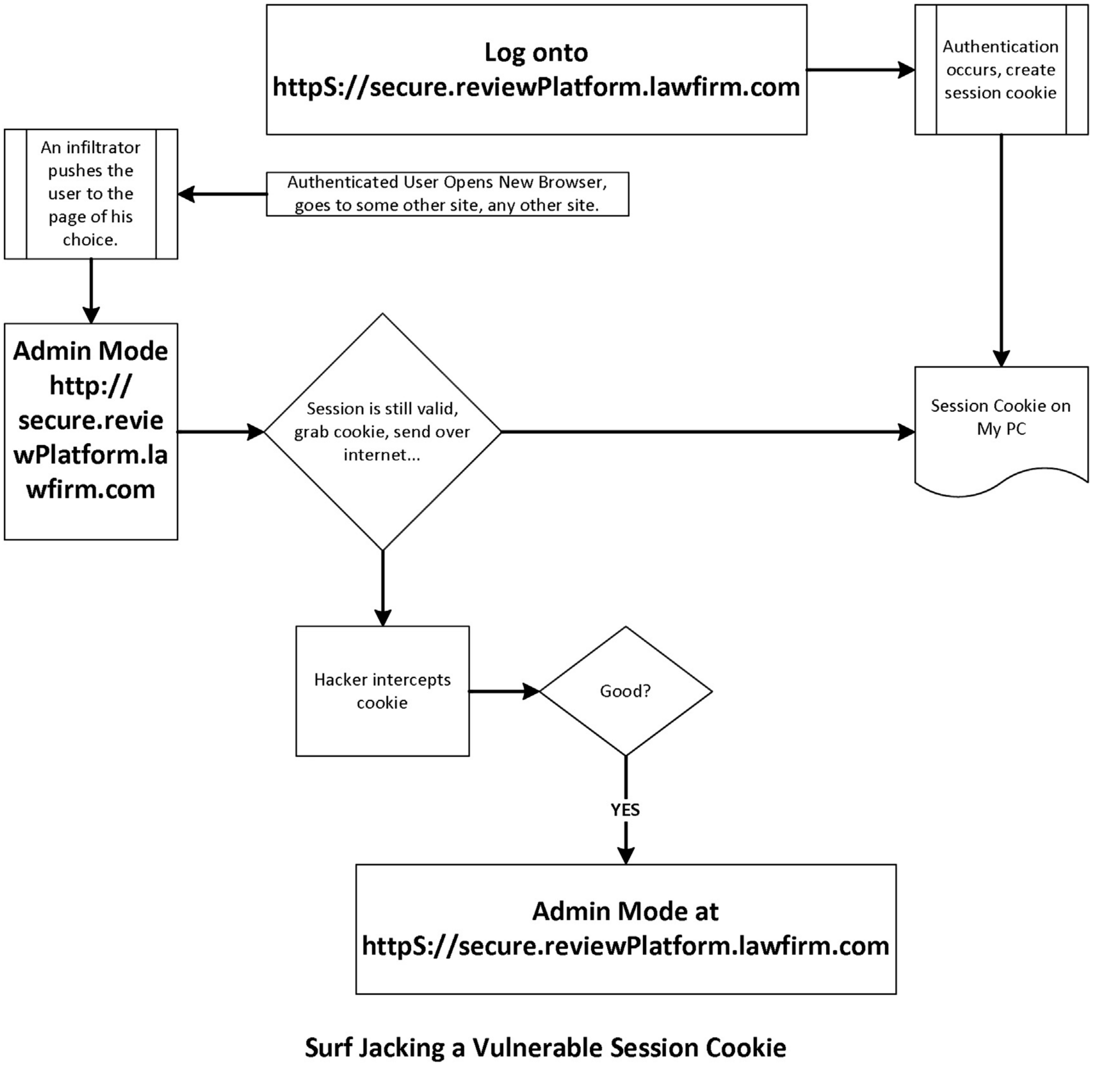

FIGURE 35.8 In a poorly secured application, the cookie becomes vulnerable to "surf-jacking," whereby a malicious user can seize control of a session.

already been scanned, so continual scanning of a file repository would be overkill if you have other intrusion countermeasures in place. Use something like a network intrusion prevention system (NIPs) for the Web and two-factor authentication on any other types of access. The reason for the scanning shown on the review repository in Figure 35.6 is to address zeroth day threats that could be lurking.

The term *zeroth* day is, in reality, somewhat misleading. This author once had a desktop that scanned clean by antivirus tool A (I KNEW it was infected). Scanning the machine again using Antivirus tool B (and then C, D, E, and F) also revealed nothing. The only thing to do was to shut the machine down and preserve it. A month later a scan, using the exact same scanning tools but with updated definition, located the virus.

Sometimes the scanners we are using just don't have the definitions yet. DO require scanning of an adequately protected file repository when virus definitions are updated. In particular, be cognizant of virus definitions that cover loose files. Scanning the file repository in a targeted way can reduce the load on the system. For example, when an antivirus company releases a signature update that specifically addresses infected Excel spreadsheets, scan all spreadsheets with that particular signature.

Scanning activities should also occur in a staging area whenever new loads of files arrive, regardless of the source, but especially ones that have been processed without regard to any sort of an EDRM security zone model. This chapter puts forth a zoned security model that underpins the entire EDRM: Any processing vendor that operates as though it is an island should be cause for concern.

Securing Zone 6: Production and Presentation

These two areas of the EDRM are zoned together in this model. In this model, there are two types of production. The first kind is called a “disclosure” in some countries. In the United States, it is just “discovery.” Effectively, the first kind of production is the release of information in the format agreed to in the pre-discovery “meet and confer” conference to the opposing counsel. Production data that is to be delivered to opposing counsel should be delivered in a compressed and encrypted format. 7Zip is one such tool that is both free and effective. It allows for compressing in several different formats, and it offers all of the flexibility needed to compress large amounts of data. Alternatively, whole drive encryption may be more efficient, at least from a workflow perspective, and the drives can be locked in TSA-approved containers and shipped overnight.

Other kinds of production include privilege log, attorneys’ eyes only logs, and other same-side productions, which may be delivered to other counsels, expert witnesses, or other vendors for further processing. Use a media tracking application in conjunction with a labeling system (RFID or bar code) to control media. The location and who has handled or come into contact with electronic discovery will help to determine the source of a security weakness; it will also help with the continued, ongoing assessment of risk.

In the EDRM, the presentation vertical simply refers to courtroom technologies and the presentation of documents and other information. Several software products will allow things like video, document, and transcript presentation via a projector. In the past, law firms would spend thousands of dollars on large, printed, foam-board charts and graphs to make their points to juries and judges. This trend has declined in the past decade, with more and more attorneys bringing laptops into the courtroom. There are few courts that are not media ready, wired for sound, with microphone and video, and with strategically placed monitors and projectors.

The quality of monitors, however, should be checked, as should all systems. Some courtrooms are slow to upgrade and will either not have monitors available or will make available monitors that are of such poor quality that they can hardly be viewed. This may swing the decision as to whether or not a mobile network should be set up in the courtroom. There will rarely be hard-wired network access available, though there may be a public wireless point that will likely be shared. Secure any wireless access by ensuring that a software firewall exists on any laptops that will be entering the court room.

Security

Zone 6 security, then, involves a thorough tracking of media and securing any deliveries of data or findings to a separate vendor entity for processing into a more presentable format. At this stage, the e-discovery process is complete. It is show time. If the documents are in the production, they will soon be out of the control of the enterprise. Questioning and ensuring the security of these documents should not be overlooked: The attorneys may not know, or even think, to worry about this. It is up to the director of electronic discovery at the originating corporate level to follow the progress, to ensure security at every touch point, and to ensure that a program is in place that educates any attorneys as to the importance of data security and what they can do to help. Insist on encryption and on secure storage of delivered productions. This is not an unreasonable thing to do. Requesting “attorney’s eyes only” is also not abnormal. Confidentiality and nondisclosure agreements should be signed and understood by anyone who will come into contact with sensitive, proprietary, and confidential corporate data.

3. SUMMARY

This chapter has endeavored to condense the experiences of over a decade of forensic, litigation, security, discovery, and software design and use-cases into some 40 pages. It has attempted to do this in such a way as to lay a foundation of understanding. Through learning the business and understanding the ins-and-outs of it, a proper security framework for individually unique enterprises and unique legal cases can be established.

The industry is rapidly changing. New technologies are emerging, and companies, such as kCura, Recommind, and AccessData, which were once microshops, are growing and absorbing more of the EDRM’s functions into their offerings. As these platforms grow, they will inevitably become more robust and will offer the full life cycle in one product, or suite. Ultimately, the organizations that are suing each other will experience the greatest security when the data can be kept and processed in as few disparate locations as possible.

The preceding will only be achieved by consolidating and collapsing the security zones to the point where there only exist the corporate information system and a legal system whereby attorneys are able to securely present their work in a court of law. If the EDRM can be run in such a way that *only* responsive data leaves the building, then the surface area of exposure shrinks and security increases.

Finally, let’s move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and an optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor’s Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The field of e-discovery does not relate to litigation as a whole.
2. True or False? The framework of the EDRM begins with information security.
3. True or False? Certain types of organizations are more likely than others to be prone to litigation.
4. True or False? There are loopholes in any external facing system.
5. True or False? The EDRM model breaks identification into the same phase of e-Discovery as information management.

Multiple Choice

1. Finding better ways to improve what you are doing is known as:
   - **A.** process.
   - **B.** standardization.
   - **C.** data retention.
   - **D.** evolution.
   - **E.** security.
2. Defining and understanding your information flow is known as:
   - **A.** evolution.
   - **B.** standardization.
   - **C.** data retention.
   - **D.** process.
   - **E.** security.
3. Making sure everyone uses the same software, stores information in the same places, and uses approved technology for information transmittals is known as:
   - **A.** evolution.
   - **B.** data retention.
   - **C.** standardization.
   - **D.** process.
   - **E.** security.
4. Ensuring that you know your data isn't walking out your front (or back) door, is known as:
   - **A.** security.
   - **B.** data retention.
   - **C.** standardization.s
   - **D.** process.
   - **E.** evolution.
5. Ensuring that you are keeping what you want to keep, destroying what you don't want, and backing up data at risk is known as:
   - **A.** security.
   - **B.** data retention.
   - **C.** standardization.
   - **D.** data destruction.
   - **E.** all of the above.

EXERCISE

Problem

Can an organization's internal IT staff conduct an investigation and extract electronic evidence?

Hands-On Projects

Project

What happens to electronic information after it is deleted?

Case Projects

Problem

What can an organization do immediately to safeguard the integrity and admissibility of electronic evidence?

Optional Team Case Project

Problem

What is spoliation, and how can an organization protect against it?

Chapter 36

Network Forensics

Yong Guan
Iowa State University

1. SCIENTIFIC OVERVIEW

With the phenomenal growth of the Internet, more and more people enjoy and depend on the convenience of its provided services. The Internet has spread rapidly almost all over the world. Up to December 2006, the Internet had been distributed to over 233 countries and world regions and had more than 1.09 billion users.[1] Unfortunately, the wide use of computers and the Internet also opens doors to cyber attackers. There are different kinds of attacks that an end user of a computer or Internet can meet. For instance, there may be various viruses on a hard disk, several backdoors open in an operating system, or a lot of phishing emails in an emailbox. According to the annual *Computer Crime Report* of the Computer Security Institute (CSI) and the U.S. Federal Bureau of Investigation (FBI), released in 2006, cyber attacks cause massive money losses each year.

However, the FBI/CSI survey results also showed that a low percentage of cyber crime cases have been reported to law enforcement (in 1996, only 16%; in 2006, 25%), which means that in reality, the vast majority of cyber criminals are never caught or prosecuted. Readers may ask why this continues to happen. Several factors contribute to this fact:

- In many cases, businesses are often reluctant to report and publicly discuss cyber crimes related to them. The concern of negative publicity becomes the number-one reason because it may attract other cyber attackers, undermine the confidence of customers, suppliers, and investors, and invite the ridicule of competitors.
- Generally, it is much harder to detect cyber crimes than crimes in the physical world. There are various antiforensics techniques that can help cyber criminals evade detection, such as information-hiding techniques (steganography, covert channels), anonymity proxies, stepping stones, and botnets. Even more challenging, cyber criminals are often insiders or employees of the organizations themselves.
- Attackers may walk across the boundaries of multiple organizations and even countries. To date, the lack of effective solutions has significantly hindered efforts to investigate and stop the rapidly growing cyber criminal activities. It is therefore crucial to develop a forensically sound and efficient solution to track and capture these criminals.

Here we discuss the basic principles and some specific forensic techniques in attributing real cyber criminals.

2. THE PRINCIPLES OF NETWORK FORENSICS

Network forensics can be generally defined as a science of discovering and retrieving evidential information in a networked environment about a crime in such a way as to make it admissible in court. Different from intrusion detection, all the techniques used for the purpose of network forensics should satisfy both legal and technical requirements. For example, it is important to guarantee whether the developed network forensic solutions are practical and fast enough to be used in high-speed networks with heterogeneous network architecture and devices. More important, they need to satisfy general forensics principles such as the rules of evidence and the criteria for admissibility of novel scientific evidence (such as the *Daubert* criteria).[2,3,4] The five rules are that evidence must be:

- *Admissible*. Must be able to be used in court or elsewhere.

1. Internet World Stats, www.internetworldstats.com.

2. G. Palmer, "A road map for digital forensic research," Digital Forensic Research Workshop (DFRWS), Final Report, Aug. 2001.
3. C. M. Whitcomb, "An historical perspective of digital evidence: A forensic scientist's view," IJDE, 2002.
4. S. Mocas, "Building theoretical underpinnings for digital forensics research," Digital Investigation, Vol. 1, pp. 61–68, 2004.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00036-2

- *Authentic*. Evidence relates to incident in relevant way.
- *Complete*. No tunnel vision, exculpatory evidence for alternative suspects.
- *Reliable*. No question about authenticity and veracity.
- *Believable*. Clear, easy to understand, and believable by a jury.

The evidence and the investigative network forensics techniques should satisfy the criteria for admissibility of novel scientific evidence (*Daubert v. Merrell*):

- Whether the theory or technique has been reliably tested
- Whether the theory or technique has been subject to peer review and publication
- What is the known or potential rate of error of the method used?
- Whether the theory or method has been generally accepted by the scientific community

The investigation of a cyber crime often involves cases related to homeland security, corporate espionage, child pornography, traditional crime assisted by computer and network technology, employee monitoring, or medical records, where privacy plays an important role.

There are at least three distinct communities within digital forensics: law enforcement, military, and business and industry, each of which has its own objectives and priorities. For example, prosecution is the primary objective of the law enforcement agencies and their practitioners and is often done after the fact. Military operations' primary objective is to guarantee the continuity of services, which often have strict real-time requirements. Business and industry's primary objectives vary significantly, many of which want to guarantee the availability of services and put prosecution as a secondary objective.

Usually there are three types of people who use digital evidence from network forensic investigations: police investigators, public investigators, and private investigators. The following are some examples:

- Criminal prosecutors. Incriminating documents related to homicide, financial fraud, drug-related records.
- Insurance companies. Records of bill, cost, services to prove fraud in medical bills and accidents.
- Law enforcement officials. Require assistance in search warrant preparation and in handling seized computer equipment.
- Individuals. To support a possible claim of wrongful termination, sexual harassment, or age discrimination.

The primary activities of network forensics are investigative in nature. The investigative process encompasses the following:

- Identification
- Preservation
- Collection
- Examination
- Analysis
- Presentation
- Decision

In the following discussion, we focus on several important network forensic areas (see checklist: "An Agenda For Action For Network Forensics").

An Agenda for Action for Network Forensics

The cyber forensics specialist should ensure the following are adhered to (Check All Tasks Completed):

_____**1.** Provide expert data visualization techniques to the problem of network data pattern analysis.

_____**2.** Apply standard research and analysis techniques to datasets provided by a company or organization.

_____**3.** Apply the lessons learned from company-provided datasets to open datasets as the research advances.

_____**4.** Provide initial datasets, project initiation, and training in network traffic datasets and analysis techniques.

_____**5.** Provide expert network forensical rule-based algorithms for incorporation by researchers.

_____**6.** Repeatedly test and verify new visualization techniques and procedures to ensure that new patterns are, in fact, accurate representations of designated activities.

_____**7.** Develop a test database.

_____**8.** Develop a design methodology for visualizing test data.

_____**9.** Develop a query interface to the database.

_____**10.** Map data structures to a visualization model.

_____**11.** Build a prototype.

_____**12.** Refine a prototype.

_____**13.** Incorporate live Internet data.

_____**14.** Test live Internet data.

_____**15.** Deliver a final build.

_____**16.** Produce new visualization techniques to streamline and enhance analysis of network forensic data.

_____**17.** Produce a Web browser compatible prototype that demonstrates these techniques to visualize and query vast amounts of data. The resulting interactive visualization interface will advance the usability of the system, solve the volumetric problem with analyzing these datasets, and advance the adaptation of the solution in the INFOSEC market.

_____**18.** Routinely archive all e-mail as it is received on your server for a certain period of time (say, 30–60 days).
_____**19.** Clear the archives after an additional specified time.
_____**20.** Physically segregate the back-up copies of the e-mail system from back-ups of the rest of the computer system.
_____**21.** Automatically erase e-mail from the computer system, including back-ups, after a short period (15–30 days).
_____**22.** Apply uniform retention and deletion standards and features outside the server to workstations and laptops.
_____**23.** Formulate and distribute a statement that the automatic deletion of electronic records will be suspended and steps taken to preserve records in the event of investigation or litigation.
_____**24.** Maintain an appropriate SOP document. All agencies that seize and/or examine digital evidence must do this.
_____**25.** Clearly set forth in this SOP document all elements of an agency's policies and procedures concerning digital evidence, which must be issued under the agency's management authority.
_____**26.** Review the SOPs on an annual basis to ensure their continued suitability and effectiveness.
_____**27.** Make sure that the procedures that you use are generally accepted in the field or supported by data gathered and recorded in a scientific manner.
_____**28.** Maintain written copies of appropriate technical procedures.
_____**29.** Use hardware and software that is appropriate and effective for the seizure or examination procedure.
_____**30.** Record all activity relating to the seizure, storage, examination, or transfer of digital evidence in writing.
_____**31.** Make sure that all digital evidence is available for review and testimony.
_____**32.** Make sure that any action that has the potential to alter, damage, or destroy any aspect of original evidence is performed by qualified persons in a forensically sound manner.
_____**33.** Be alert. One of the best ways to ensure that your network is secure is to keep abreast of developing threats. Security experts agree that ignorance is the most detrimental security problem. Most hacks occur because someone wasn't paying attention. Web sites such as the CERT home page (http://www.cert.org) are excellent places to get current information.
_____**34.** Apply all service patches. Many companies will sit on patches rather than put them to use. Others are not diligent enough about searching for and downloading the latest virus definitions. Smart hackers bank on the negligence of others.
_____**35.** Limit port access. Although just about any application that uses TCP requires a port, you can minimize exposure by limiting the number of ports accessible through a firewall. NNTP (Network News Transport Protocol) is an excellent example: Unless your shop requires newsgroup access, port 119 should be shut down.
_____**36.** Eliminate unused user IDs and change existing passwords. Poor maintenance is almost as dangerous as ignorance.
_____**37.** Make sure that system administrators routinely audit and delete any idle user IDs.
_____**38.** Make sure that in order to limit the likelihood of successful random guessing, that all user and system passwords be system-generated or system-enforced.
_____**39.** Avoid the use of SNMP across the firewall.
_____**40.** Check routers to make sure they do not respond to SNMP commands originating outside the network.
_____**41.** Secure remote access. Try to break into your own network. You can learn a lot by hacking into your own system.
_____**42.** Test your packet-filtering scheme. If you can gain access to your systems from a workstation outside your network, you can easily test your packet-filtering scheme without any outside exposure. If you do spot a weakness, you'll be one step ahead of the hackers.
_____**43.** Ask a consultant when in doubt. If you don't have the technical wherewithal in-house or if your staff is too busy working on other projects, don't hesitate to call in a consultant. Many companies offer security assessment and training services.
_____**44.** Assess your company's networking needs and shut down any ports that aren't necessary for day-to-day operations, such as port 53 for DNS access and port 119 for NNTP (Network News Transfer Protocol) services.
_____**45.** Be sure to eliminate unused user IDs and to avoid provisioning SNMP services through the firewall.

3. ATTACK TRACEBACK AND ATTRIBUTION

When we face the cyber attacks, we can detect them and take countermeasures. For instance, an intrusion detection system (IDS) can help detect attacks; we can update operating systems to close potential backdoors; we can install antivirus software to defend against many known viruses. Although in many cases we can detect attacks and mitigate their damage, it is hard to find the real attackers/criminals. However, if we don't trace back to the attackers, they can always conceal themselves and launch new attacks. If we have the ability to find and punish the

attackers, we believe this will help significantly reduce the attacks we face every day.

Why is traceback difficult in computer networks? One reason is that today's Internet is stateless. There is too much data in the Internet to record it all. For example, a typical router only forwards the passed packets and does not care where they are from; a typical mail transfer agent (MTA) simply relays emails to the next agent and never minds who is the sender. Another reason is that today's Internet is almost an unauthorized environment. Alice can make a VoIP call to Bob and pretend to be Carol; an attacker can send millions of emails using your email address and your mailbox will be bombed by millions of replies. Two kinds of attacks are widely used by attackers and also interesting to researchers all over the world. One is IP spoofing; the other is the stepping-stone attack. Each IP packet header contains the source IP address. Using IP spoofing, an attacker can change the source IP address in the header to that of a different machine and thus avoid traceback.

In a stepping-stone attack, the attack flow may travel through a chain of stepping stones (intermediate hosts) before it reaches the victim. Therefore, it is difficult for the victim to know where the attack came from except that she can see the attack traffic from the last hop of the stepping-stone chain. Figure 36.1 shows an example of IP stepping-stone attack.

Next we introduce the existing schemes to trace back IP spoofing attacks, then we discuss current work on stepping-stone attack attribution.

IP Traceback

Here we review major existing IP traceback schemes that have been designed to trace back to the origin of IP packets through the Internet. We roughly categorize them into four primary classes:

- Active probing[5,6]
- ICMP traceback[7,8,9]
- Packet marking[10,11,12,13,14]
- Log-based traceback[15,16,17,18]

Active Probing

Stone[19] proposed a traceback scheme called *CenterTrack*, which selectively reroutes the packets in question directly from edge routers to some special tracking routers. The tracking routers determine the ingress edge router by observing from which tunnel the packet arrives. This approach requires the cooperation of network administrators, and the management overhead is considerably large.

Burch and Cheswick[20] outlined a technique for tracing spoofed packets back to their actual source without relying on the cooperation of intervening ISPs. The victim actively changes the traffic in particular links and observes the influence on attack packets, and thus can determine where the attack comes from. This technique cannot work well on distributed attacks and requires that the attacks remain active during the time period of traceback.

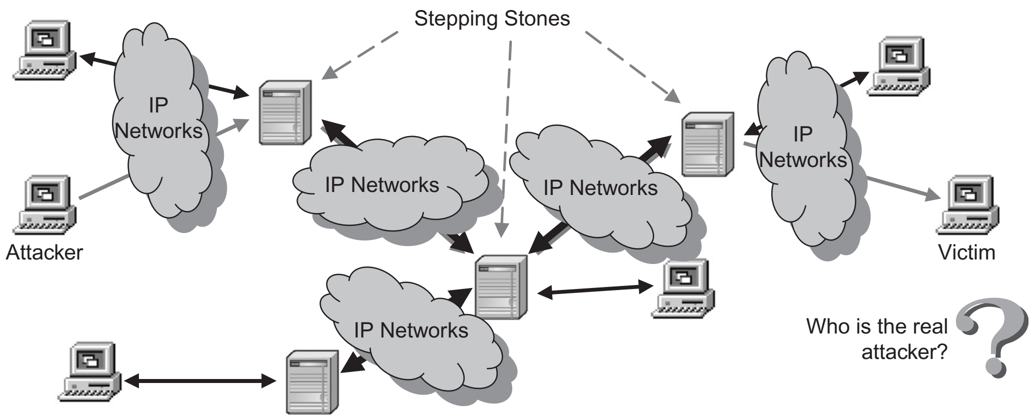

FIGURE 36.1 Stepping-stone attack attribution.

ICMP Traceback (iTrace)

Bellovin[21] proposed a scheme named *iTrace* to trace back using ICMP messages for authenticated IP marking. In this scheme, each router samples (with low probability) the forwarding packets, copies the contents into a special ICMP traceback message, adds its own IP address as well as the IP of the previous and next-hop routers, and forwards the packet to either the source or destination address. By combining the information obtained from several of these ICMP messages from different routers, the victim can then reconstruct the path back to the origin of the attacker.

A drawback of this scheme is that it is much more likely that the victim will get ICMP messages from routers nearby than from routers farther away. This implies that most of the network resources spent on generating and utilizing iTrace messages will be wasted. An enhancement of iTrace, called *Intention-Driven iTrace*, has been proposed.[22,23] By introducing an extra "intention-bit," it is possible for the victim to increase the probability of receiving iTrace messages from remote routers.

Packet Marking

Savage et al.[24] proposed a *Probabilistic Packet Marking* (PPM) scheme. Since then several other PPM-based schemes have been developed.[25,26,27] The baseline idea of PPM is that routers probabilistically write partial path information into the packets during forwarding. If the attacks are made up of a sufficiently large number of packets, eventually the victim may get enough information by combining a modest number of marked packets to reconstruct the entire attack path. This allows victims to locate the approximate source of attack traffic without requiring outside assistance.

The *Deterministic Packet Marking* (DPM) scheme proposed by Belenky and Ansari[28] involves marking each individual packet when it enters the network. The packet is marked by the interface closest to the source of the packet on the edge ingress router. The mark remains unchanged as long as the packet traverses the network. However, there is no way to get the whole paths of the attacks.

Dean et al.[29] proposed an *Algebraic Packet Marking* (APM) scheme that reframes the traceback problem as a polynomial reconstruction problem and uses techniques from algebraic coding theory to provide robust methods of transmission and reconstruction. The advantage of this

scheme is that it offers more flexibility in design and more powerful techniques that can be used to filter out attacker-generated noise and separate multiple paths. But it shares similarity with PPM in that it requires a sufficiently large number of attack packets.

Log-Based Traceback

The basic idea of log-based traceback is that each router stores the information (digests, signature, or even the packet itself) of network traffic through it. Once an attack is detected, the victim queries the upstream routers by checking whether they have logged the attack packet in question. If the attack packet's information is found in a given router's memory, that router is deemed to be part of the attack path. Obviously, the major challenge in log-based traceback schemes is the storage space requirement at the intermediate routers.

Matsuda et al.[30] proposed a hop-by-hop log-based IP traceback method. Its main features are a logging *packet feature* that is composed of a portion of the packet for identification purposes and an algorithm using a data-link identifier to identify the routing of a packet. However, for each received packet, about 60 bytes of data should be recorded. The resulting large memory space requirement prevents this method from being applied to high-speed networks with heavy traffic.

Although today's high-speed IP networks suggest that classical log-based traceback schemes would be too prohibitive because of the huge memory requirement, logbased traceback became attractive after Bloom filter-based (i.e., hash-based) traceback schemes were proposed. *Bloom filters* were presented by Burton H. Bloom[31] in 1970 and have been widely used in many areas such as database and networking.[32] A Bloom filter is a spaceefficient data structure for representing a set of elements to respond to membership queries. It is a vector of bits that are all initialized to the value 0. Then each element is inserted into the Bloom filter by hashing it using several independent uniform hash functions and setting the corresponding bits in the vector to value 1. Given a query as to whether an element is present in the Bloom filter, we hash this element using the same hash functions and check whether all the corresponding bits are set to 1. If any one of them is 0, then undoubtedly this element is not stored in the filter. Otherwise, we would say that it is present in the filter, although there is a certain probability that the element is determined to be in the filter though it is actually not. Such false cases are called *false positives*.

The space-efficiency of Bloom filters is achieved at the cost of a small, acceptable false-positive rate. Bloom filters were introduced into the IP traceback area by Snoeren et al.[33] They built a system named the *Source Path Isolation Engine* (SPIE), which can trace the origin of a single IP packet delivered by the network in the recent past. They demonstrated that the system is effective, space-efficient, and implementable in current or next-generation routing hardware. Bloom filters are used in each SPIE-equipped router to record the digests of all packets received in the recent past. The digest of a packet is exactly several hash values of its nonmutable IP header fields and the prefix of the payload. Strayer et al.[34] extended this traceback architecture to IP-v6. However, the inherent false positives of Bloom filters caused by unavoidable collisions restrain the effectiveness of these systems. To reduce the impact of unavoidable collisions in Bloom filters, Zhang and Guan[35] propose a topologyaware single-packet IP traceback system, namely TOPO. The router's local topology information, that is, its immediate predecessor information, is utilized. The performance analysis shows that TOPO can reduce the number and scope of unnecessary queries and significantly decrease false attributions. When Bloom filters are used, it is difficult to decide their optimal control parameters *a priori*. They designed a *k*-adaptive mechanism that can dynamically adjust the parameters of Bloom filters to reduce the false-positive rate.

Shanmugasundaram et al.[36] proposed a *payload attribution system* (PAS) based on a *hierarchical Bloom filter* (HBF). HBF is a Bloom filter in which an element is inserted several times using different parts of the same element. Compared with SPIE, which is a packet-digesting scheme, PAS only uses the payload excerpt of a packet. It is useful when the packet header is unavailable.

Li et al.[37] proposed a Bloom filter-based IP trace-back scheme that requires an order of magnitude smaller processing and storage cost than SPIE, thereby being able to scale to much higher link speed. The baseline idea of their approach is to sample and log a small percentage of packets, and 1 bit packet marking is used in their sampling scheme. Therefore, their traceback scheme combines packet marking and packet logging together. Their simulation results showed that the traceback scheme can achieve high accuracy and scale well to a large number of attackers. However, as the authors also pointed out, because of the low sampling rate, their scheme is no longer capable of tracing one attacker with only one packet.

Stepping-Stone Attack Attribution

Ever since the problem of detecting stepping stones was first proposed by Staniford-Chen and Heberlein,[38] several approaches have been proposed to detect encrypted stepping-stone attacks.

The ON/OFF based approach proposed by Zhang and Paxson[39] is the first timing-based method that can trace stepping stones, even if the traffic were to be encrypted. In their approach, they calculated the correlation of different flows by using each flow's OFF periods. A flow is considered to be in an OFF period when there is no data traffic on it for more than a time period threshold. Their approach comes from the observation that two flows are in the same connection chain if their OFF periods coincide.

Yoda and Etoh[40] presented a deviation-based approach for detecting stepping-stone connections. The deviation is defined as the difference between the average propagation delay and the minimum propagation delay of two connections. This scheme comes from the observation that the deviation for two unrelated connections is large enough to be distinguished from the deviation of connections in the same connection chain.

Wang et al.[41] proposed a correlation scheme using interpacket delay (IPD) characteristics to detect stepping stones. They defined their correlation metric over the IPDs in a sliding window of packets of the connections to be correlated. They showed that the IPD characteristics may be preserved across many stepping stones.

Wang and Reeves[42] presented an active watermark scheme that is designed to be robust against certain delay perturbations. The watermark is introduced into a connection by slightly adjusting the interpacket delays of selected packets in the flow. If the delay perturbation is not quite large, the watermark information will remain along the connection chain. This is the only active steppingstone attribution approach.

Strayer et al.[43] presented a State-Space algorithm that is derived from their work on wireless topology discovery. When a new packet is received, each node is given a weight that decreases as the elapsed time from the last packet from that node increases. Then the connections on the same connection chain will have higher weights than other connections.

However, none of these previous approaches can effectively detect stepping stones when delay and chaff perturbations exist simultaneously. Although no experimental data is available, Donoho et al.[44] indicated that there are theoretical limits on the ability of attackers to disguise their traffic using evasions for sufficiently long connections. They assumed that the intruder has a maximum delay tolerance, and they used wavelets and similar multiscale methods to separate the short-term behavior of the flows (delay or chaff) from the long-term behavior of the flows (the remaining correlation). However, this method requires the intrusion connections to remain for long periods, and the authors never experimented to show the effectiveness against chaff perturbation. These evasions consist of local jittering of packet arrival times and the addition of superfluous packets.

Blum et al.[45] proposed and analyzed algorithms for stepping-stone detection using ideas from computational learning theory and the analysis of random walks. They achieved provable (polynomial) upper bounds on the

45. A. Blum, D. Song, and S. Venkataraman, "Detection of interactive stepping stones: Algorithms and confidence bounds," in *Proceedings of the* 7*th International Symposium on Recent Advances in Intrusion Detection* (RAID 2004), Sept. 2004.

number of packets needed to confidently detect and identify stepping-stone flows with proven guarantees on the false positives and provided lower bounds on the amount of chaff that an attacker would have to send to evade detection. However, their upper bounds on the number of packets required is large, while the lower bounds on the amount of chaff needed for attackers to evade detection is very small. They did not discuss how to detect stepping stones without enough packets or with large amounts of chaff and did not show experimental results.

Zhang et al.[46] proposed and analyzed algorithms that represent that attackers cannot always evade detection only by adding limited delay and independent chaff perturbations. They provided the upper bounds on the number of packets needed to confidently detect stepping-stone connections from nonstepping stone connections with any given probability of false attribution.

Although there have been many stepping-stone attack attribution schemes, there is a lack of comprehensive experimental evaluation of these schemes. Therefore, there are no objective, comparable evaluation results on the effectiveness and limitations of these schemes. Xin et al.[47] designed and built a scalable testbed environment that can evaluate all existing stepping-stone attack attribution schemes reproducibly, provide a stable platform for further research in this area, and be easily reconfigured, expanded, and operated with a user-friendly interface. This testbed environment has been established in a dedicated stepping-stone attack attribution research laboratory. An evaluation of proposed stepping-stone techniques is currently under way.

A group from Iowa State University proposed the first effective detection scheme to detect attack flows with both delay and chaff perturbations. A scheme named "datatick" is proposed that can handle significant packet merging/splitting and can attribute multiple application layer protocols (e.g., X-Windows over SSH, Windows Remote Desktop, VNC, and SSH). A scalable testbed environment is also established that can evaluate all existing stepping-stone attack attribution schemes reproducibly. A group of researchers from North Carolina State University and George Mason University utilizes timing-based watermarking to trace back stepping-stone attacks. They have proposed schemes to handle repacketization of the attack flow and a "centroid-based" watermarking scheme to detect attack flows with chaff. A group from Johns Hopkins University demonstrates the feasibility of a "post-mortem" technique for traceback through indirect attacks. A group from Telcordia Technologies proposed a scheme that reroutes the attack traffic from uncooperative networks to cooperative networks such that the attacks can be attributed. The BBN Technologies' group integrates single-packet traceback and stepping-stone correlation. A distributed traceback system called FlyTrap is developed for uncooperative and hostile networks. A group from Sparta integrates multiple complementary traceback approaches and tests them in a TOR anonymous system.

A research project entitled Tracing VoIP Calls through the Internet, led by Xinyuan Wang from George Mason University, aims to investigate how VoIP calls can be effectively traced. Wang et al. proposed to use the watermarking technology in stepping-stone attack attribution into VoIP attribution and showed that VoIP calls can still be attributed.[48]

Strayer et al. has been supported by the U.S. Army Research Office to research how to attribute attackers using botnets. Their approach for detecting botnets is to examine flow characteristics such as bandwidth, duration, and packet timing, looking for evidence of botnet command and control activity.[49]

4. CRITICAL NEEDS ANALYSIS

Although large-scale cyber terrorism seldom happens, some cyber attacks have already shown their power in damaging homeland security. For instance, on October 21, 2002, all 13 Domain Name Server (DNS) root name servers sustained a DoS attack.[50] Some root name servers were unreachable from many parts of the global Internet due to congestion from the attack traffic. Even now, we do not know the real attacker and what his intention was.

Besides the Internet itself, many sensitive institutions, such as the U.S. power grid, nuclear power plants, and airports, may also be attacked by terrorists if they are connected to the Internet, although these sites have been carefully protected physically. If the terrorists want to launch large-scale attacks targeting these sensitive institutions through the Internet, they will probably have to try several times to be successful. If we only sit here and do not fight back, they will finally find our vulnerabilities

and reach their evil purpose. However, if we can attribute them to the source of attacks, we can detect and arrest them before they succeed.

Although there have been a lot of traceback and attribution schemes on IP spoofing and stepping-stone attacks, we still have a lot of open issues in this area. The biggest issue is the deployment of these schemes. Many schemes (such as packet marking and log-based traceback) need the change of Internet protocol on each intermediate router. Many schemes need many network monitors placed all over the world. These are very difficult to implement in the current Internet without support from government, manufacturers, and academics. It is necessary to consider traceback demands when designing and deploying next-generation networks.

5. RESEARCH DIRECTIONS

There are still some open problems in attack traceback and attribution.

VoIP Attribution

Like the Internet, the Voice over Internet Protocol (VoIP) also provides unauthorized services. Therefore, some security issues existing in the Internet may also appear in VoIP systems. For instance, a phone user may receive a call with a qualified caller ID from her credit-card company, so she answers the critical questions about Social Security number, data of birth, and so on. However, this call actually comes from an attacker who fakes the caller ID using a computer. Compared with a Public Switched Telephone Network (PSTN) phone or mobile phone, IP phones lack monitoring. Therefore, it is desirable to provide schemes that can attribute or trace back to the VoIP callers.

Tracking Botnets

A botnet is a network of compromised computers, or bots, commandeered by an adversarial botmaster. Botnets usually spread through viruses and communicate through the IRC channel. With an army of bots, bot controllers can launch many attacks, such as spam, phishing, key logging, and denial of service. Today more and more scientists are interested in how to detect, mitigate, and trace back botnet attacks.

Traceback in Anonymous Systems

Another issue is that there exist a lot of anonymous systems available all over the world, such as Tor.[51] Tor is a toolset for anonymizing Web browsing and publishing, instant messaging, IRC, SSH, and other applications that use TCP. It provides anonymity and privacy for legal users, and at the same time, it is a good platform via which to launch stepping-stone attacks. Communications over Tor are relayed through several distributed servers called *onion routers*. So far there are more than 800 onion routers all over the world. Since Tor may be seen as a special stepping-stone attack platform, it is interesting to consider how to trace back attacks over Tor.

Online Fraudster Detection and Attribution

One example is the auction frauds on eBay-like auction systems. In the past few years, Internet auctions have become a thriving and very important online business. Compared with traditional auctions, Internet auctions virtually allow everyone to sell and buy anything at anytime from anywhere, at low transaction fees. However, the increasing number of cases of fraud in Internet auctions has harmed this billion-dollar worldwide market. Due to the inherent limitation of information asymmetry in Internet auction systems, it is very hard, if not impossible, to discover all potential (committed and soon to be committed) frauds. Auction frauds are reported as ascending in recent years and have become serious problems. The Internet Crime Complaint Center (IC3) and Internet FraudWatch have both reported Internet auction frauds as the most prevalent type of Internet fraud.[52,53] Internet FraudWatch reported that auction fraud represented 34% (the highest percentage) of total Internet frauds in 2006, resulting in an average loss of $1,331. Internet auction houses had tried to prevent frauds by using certain types of reputation systems, but it has been shown that fraudulent users are able to manipulate these reputation systems. It is important that we develop the capability to detect and attribute auction fraudsters.

Tracing Phishers

Another serious problem is the fraud and identity theft that result from phishing, pharming, and email spoofing of all types. Online users are lured to a faked web site and tricked to disclose sensitive credentials such as passwords, Social Security numbers, and credit-card numbers. The phishers collect these credentials in order to illegitimately gain access to the user's account and cause financial loss or other damages to the user. In the past, phishing attacks often involve various actors as a part of

a secret criminal network and take approaches similar to those of money laundering and drug trafficking. Tracing phishers is a challenging forensic problem and the solutions thereof would greatly help law enforcement practitioners and financial fraud auditors in their investigation and deterrence efforts.

Tracing Illegal Content Distributor in P2P Systems

Peer-to-peer (P2P) file sharing has gained popularity and achieved a great success in the past 15 years. Though the well-known and popular P2P file sharing applications such as BitTorrent (BT), eDonkey, and Foxy may vary from region to region, the trend of using P2P networks can be seen almost everywhere. In North America, a recent report stated that around 41%–44% of all bandwidth was used up by P2P file transfer traffic. With the increasing amount of sensitive documents and files accidentally shared through P2P systems, it is important to develop forensic solutions for locating initial illegal content uploaders in P2P systems. However, one technique would not be applicable to all P2P systems due to their architectural and algorithmic differences among different P2P systems. There are many legal and technical challenges for tracing illegal content distributors in P2P systems.

6. SUMMARY

Organizations should have a capability to perform computer and network forensics. Forensics is needed for various tasks within an organization, including investigating crimes and inappropriate behavior, reconstructing computer security incidents, troubleshooting operational problems, supporting due diligence for audit record maintenance, and recovering from accidental system damage. Without such a capability, an organization will have difficulty determining what events have occurred within its systems and networks, such as exposures of protected, sensitive data. Also, handling evidence in a forensically sound manner puts decision makers in a position where they can confidently take the necessary actions.

One of the most challenging aspects of network forensics is that the available data is typically not comprehensive. In many cases, if not most, some network traffic data has not been recorded and consequently has been lost. Generally, analysts should think of the analysis process as a methodical approach that develops conclusions based on the data that is available and assumptions regarding the missing data (which should be based on technical knowledge and expertise). Although analysts should strive to locate and examine all available data regarding an event, this is not practical in some cases, particularly when there are many redundant data sources. The analyst should eventually locate, validate, and analyze enough data to be able to reconstruct the event, understand its significance, and determine its impact. In many cases, additional data is available from sources other than network traffic related sources (data files or host OSs).

Organizations typically have many different sources of network traffic data. Because the information collected by these sources varies, the sources may have different value to the analyst, both in general and for specific cases. The following items describe the typical value of the most common data sources in network forensics.

IDS Software

IDS data is often the starting point for examining suspicious activity. Not only do IDSs typically attempt to identify malicious network traffic at all TCP/IP layers, but also they log many data fields (and sometimes raw packets) that can be useful in validating events and correlating them with other data sources. Nevertheless, as noted previously, IDS software does produce false positives, so IDS alerts should be validated. The extent to which this can be done depends on the amount of data recorded related to the alert and the information available to the analyst about the signature characteristics or anomaly detection method that triggered the alert.

Security Event Management Software

Ideally, SEM can be extremely useful for forensics because it can automatically correlate events among several data sources, then extract the relevant information and present it to the user. However, because SEM software functions by bringing in data from many other sources, the value of SEM depends on which data sources are fed into it, how reliable each data source is, and how well the software can normalize the data and correlate events.

NFAT Software

NFAT software is designed specifically to aid in network traffic analysis, so it is valuable if it has monitored an event of interest. NFAT software usually offers features that support analysis, such as traffic reconstruction and visualization; Firewalls, Routers, Proxy Servers, and Remote Access Servers. By itself, data from these sources is usually of little value. Analyzing the data over time can indicate overall trends, such as an increase in blocked connection attempts. However, because these sources typically record little information about each event, the data provides little insight into the nature of the events. Also,

many events might be logged each day, so the sheer volume of data can be overwhelming. The primary value of the data is to correlate events recorded by other sources. For example, if a host is compromised and a network IDS sensor detected the attack, querying the firewall logs for events involving the apparent attacking IP address might confirm where the attack entered the network and might indicate other hosts that the attacker attempted to compromise. In addition, address mapping (NAT) performed by these devices is important for network forensics because the apparent IP address of an attacker or a victim might actually have been used by hundreds or thousands of hosts. Fortunately, analysts usually can review the logs to determine which internal address was in use.

DHCP Servers

DHCP servers typically can be configured to log each IP address assignment and the associated MAC address, along with a timestamp. This information can be helpful to analysts in identifying which host performed an activity using a particular IP address. However, analysts should be mindful of the possibility that attackers on an organization's internal networks falsified their MAC addresses or IP addresses, a practice known as spoofing.

Packet Sniffers

Of all the network traffic data sources, packet sniffers can collect the most information on network activity. However, sniffers might capture huge volumes of benign data as well.millions or billions of packets.and typically provide no indication as to which packets might contain malicious activity. In most cases, packet sniffers are best used to provide more data on events that other devices or software has identified as possibly malicious. Some organizations record most or all packets for some period of time so that when an incident occurs, the raw network data is available for examination and analysis. Packet sniffer data is best reviewed with a protocol analyzer, which interprets the data for the analyst based on knowledge of protocol standards and common implementations.

Network Monitoring

Network monitoring software is helpful in identifying significant deviations from normal traffic flows, such as those caused by DDoS attacks, during which, hundreds or thousands of systems launch simultaneous attacks against particular hosts or networks. Network monitoring software can document the impact of these attacks on network bandwidth and availability, as well as providing information about the apparent targets. Traffic flow data can also be helpful in investigating suspicious activity identified by other sources. For example, it might indicate whether a particular communications pattern has occurred in the preceding days or weeks.

ISP Records

Information from an ISP is primarily of value in tracing an attack back to its source. This is particularly true when the attack uses spoofed IP addresses.

Send Network Traffic to the IP Address

Organizations should not send network traffic to an apparent attacking IP address to validate its identity. Any response that is generated cannot conclusively confirm the identity of the attacking host. Moreover, if the IP address is for the attacker.s system, the attacker might see the traffic and react by destroying evidence or attacking the host sending the traffic. If the IP address is spoofed, sending unsolicited network traffic to the system could be interpreted as unauthorized use or an attack. Under no circumstances should individuals attempt to gain access to others. systems without permission.

Because network forensics can be performed for many purposes with dozens of data source types, analysts may use several different tools on a regular basis, each well-suited to certain situations. Analysts should be aware of the possible approaches to examining and analyzing network traffic data and should select the best tools for each case, rather than applying the same tool to every situation. Analysts should also be mindful of the shortcomings of tools; for example, a particular protocol analyzer might not be able to translate a certain protocol or handle unexpected protocol data (illegal data field value). It can be helpful to have an alternate tool available that might not have the same deficiency.

Network forensic analysis tools (NFAT) typically provide the same functionality as packet sniffers, protocol analyzers, and SEM software in a single product. Whereas SEM software concentrates on correlating events among existing data sources (which typically include multiple network traffic.related sources), NFAT software focuses primarily on collecting, examining, and analyzing network traffic. NFAT software also offers additional features that further facilitate network forensics, such as the following:

- Reconstructing events by replaying network traffic within the tool, ranging from an individual session (instant messaging [IM] between two users) to all sessions during a particular time period. The speed of the replaying can typically be adjusted as needed.
- Visualizing the traffic flows and the relationships among hosts. Some tools can even tie IP addresses,

domain names, or other data to physical locations and produce a geographic map of the activity.
- Building profiles of typical activity and identifying significant deviations.
- Searching application content for keywords (confidential., proprietary).

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? In many cases, businesses are often eager to report and publicly discuss cyber crimes related to them.
2. True or False? Network forensics can be generally defined as a science of discovering and retrieving evidential information in a networked environment about a crime in such a way as to make it nonadmissible in court.
3. True or False? When we face the cyber attacks, we can detect them and take countermeasures.
4. True or False? The *Deterministic Packet Marking* (DPM) scheme proposed by Belenky and Ansari[28] involves marking each general packet when it enters the network.
5. True or False? The basic idea of log-based traceback is that each router stores the information (digests, signature, or even the packet itself) of network traffic through it.

Multiple Choice

1. Like the Internet, the __________________ also provides unauthorized services.
   A. Voice over Internet Protocol (VoIP)
   B. Botnets
   C. Data retention
   D. Evolution
   E. Security
2. What is a network of compromised computers, or bots, commandeered by an adversarial botmaster.
   A. Botnet
   B. Traceback
   C. Data retention
   D. Process
   E. Security
3. ___________file sharing has gained popularity and achieved a great success in the past 15 years.:
   A. Evolution
   B. Data retention
   C. Peer-to-peer (P2P)
   D. Process
   E. Security
4. In many cases, businesses are often reluctant to report and publicly discuss ___________ related to them:
   A. Security
   B. Data retention
   C. Standardization
   D. Cyber crimes
   E. Evolution
5. Generally, it is much harder to detect cyber crimes than crimes in the:
   A. Physical world
   B. Data retention
   C. Standardization
   D. Data destruction
   E. All of the above

EXERCISE

Problem

How does network forensics help an organization pinpoint the source of intermittent performance issues and conduct investigations to identify the source of data leaks, HR violations, or security breaches?

Hands-On Projects

Project

24×7 access to all network data and network forensics mining tools, allows an organization to do what?

Case Projects

Problem

How would network forensics go about addressing a pesky intermittent network issue, benchmark application performance for SLAs, or investigate a data breach?

Optional Team Case Project

Problem

When network forensics solutions are in place, what types of forensic investigations can an organization conduct?

Chapter 37

Data Encryption

Dr. Bhushan Kapoor
California State University

Dr. Pramod Pandya
California State University

Data security is not limited to wired networks but is equally critical for wireless communications such as in Wi-Fi and cellular. A very recent case was highlighted when the Indian government requested to Research In Motion (RIM) to share the encryption algorithm used in the BlackBerry cellular device. Of course, RIM refused to share the encryption algorithm. This should demonstrate that encryption is an important technology in all forms of communication. It is hard to accept that secured systems could ever remain secured, since they are designed by us and therefore must be breakable by one of us, given enough time. Every human-engineered system must have a flaw, and it is only a matter of time before someone finds it, thus demanding new innovations by exploring applications from algebraic structures such as groups and rings, elliptic curves, and quantum physics.

Over the past 20 years we have seen classical cryptography evolve to quantum cryptography, a branch of quantum information theory. Quantum cryptography is based on the framework of quantum physics, and it is meant to solve the problem of key distribution, which is an essential component of cryptography that enables us to secure data. The key allows the data to be coded so that to decode it, one would need to know the key that was used to code it. This coding of the given data using a key is known as *encryption*, and decoding of the encrypted data, the reverse step-by-step process, is known as *decryption*. At this stage we point out that the encryption algorithm comes in two flavors: symmetric and asymmetric, of which we will get into the details later on. Securing data requires a three-pronged approach: detection, prevention, and response. Data normally resides on storage media that are accessible over a network. This network is designed with a perimeter around it, such that a single access point provides a route for inbound and outbound traffic through a router supplemented with a firewall.

Data encryption prevents data from being exposed to unauthorized access and makes it unusable. Detection enables us to monitor the activities of network users and provides a means to differentiate levels of activities and offers a possible clue to network violations. Response is equally important, since a network violation must not be allowed to be repeated. Thus the three-pronged approach is evolutionary, and therefore systems analysis and design principles must be taken into account when we design a secured data network.

1. NEED FOR CRYPTOGRAPHY

Data communication normally takes place over an unsecured channel, as is the case when the Internet provides the pathways for the flow of data. In such a case the cryptographic protocols would enable secured communications by addressing the following.

Authentication

Alice sends a message to Bob. How can Bob verify that the message originated from Alice and not from Eve pretending to be Alice? Authentication is critical if Bob is to believe the message—for example, if the bank is trying to verify your Social Security or account number.

Confidentiality

Alice sends a message to Bob. How can Bob be sure that the message was not read by Eve? For example, personal communications need to be maintained as confidential.

Integrity

Alice sends a message to Bob. How does Bob verify that Eve did not intercept the message and change its contents?

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00037-4

Nonrepudiation

Alice could send a message to Bob and later deny that she ever sent a message to Bob. In such a case, how could Bob ever determine who actually sent him the message?

2. MATHEMATICAL PRELUDE TO CRYPTOGRAPHY

We will continue to describe Alice and Bob as two parties exchanging messages and Eve as the eavesdropper. Alice sends either a character string or a binary string that constitutes her message to Bob. In mathematical terms we have the *domain* of the message. The message in question needs to be secured from the eavesdropper Eve—hence it needs to be encrypted.

Mapping or Function

The encryption of the message can be defined as *mapping* the message from the domain to its range such that the inverse mapping should recover the original message. This mapping is a mathematical construct known as the *function*.

So we have a domain, and the range of the function is defined such that the elements of the domain will always map to the range of the function, never outside it. If f represents the function, and the message $m \in$ the domain, then:

$$\mathrm{f(m) = M} \in \text{the range}$$

This function can represent, for example, swapping (shifting by k places) the characters positions in the message as defined by the function:

$$\mathrm{f(m,k) = M} \in \text{the range}$$

The inverse of this function f must recover the original message, in which case the function is invertible and one-to-one defined. If we were to apply two functions such as f followed by g, the composite function $(g \circ f)$ must be defined and furthermore invertible and one-to-one to recover the original message:

$$(\mathrm{g} \circ \mathrm{f})(\mathrm{m}) = \mathrm{g}(\mathrm{f}(\mathrm{m}))$$

We will later see that this function is an algorithm that tells the user in a finite number of ways to disguise (encrypt) the given message. The inverse function, if it does exist, would enable us to recover the original message, which is known as the decryption.

Probability

Information security is the goal of the secured data encryption; hence if the encrypted data is truly randomly distributed in the message space (range), to the hacker the encrypted message is equally likely to be in any one of the states (encrypted). This would amount to maximum entropy, so one could reasonably ask as to the likelihood of a hacker breaking the encrypted message, that is, what is the probability of an insecure event taking place? This is conceptually similar to a system being in statistical equilibrium, when it could be equally likely to be in any one of the states. This could lay the foundations of cryptoanalysis in terms of how secure the encryption algorithm is, and can it be broken in polynomial time?

Complexity

Computational complexity deals with problems that could be solved in polynomial time, for a given input. If a given encryption algorithm is known to be difficult to solve and may have a number of solutions, the hacker would have a surmountable task to solve it. Therefore, secured encryption can be examined within the scope of computational complexity to determine whether a solution exists in polynomial time. There is a class of problems that have solutions in polynomial time for a given input, designated as P. By contrast, NP is the set of all problems that have solutions in polynomial time but the correctness of the problem cannot be ascertained. Therefore, NP is a larger set containing the set P. This is useful, for it leads us to NP-completeness, which reduces the solvability of problems in class P to class NP.

Consider a simple example—a set $S = \{4, 7, 12, 1, 10\}$ of five numbers. We want any three numbers to add to 23. Each of the numbers is either selected once only or not selected. The target is 23. Is there an algorithm for the target 23? If there is one, do we have more than one solution? Let's explore whether we can add three numbers to reach a target of 25. Is there a solution for a target of 25? Does a solution exist, and can we investigate in polynomial time? We could extend this concept of computational complexity to crack encryption algorithm that is public, but the key used to encrypt and decrypt the message is kept private. So, in essence the cryptoanalysis deals with discovering the key.

3. CLASSICAL CRYPTOGRAPHY

The conceptual foundation of cryptography was laid out around 3,000 years ago in India and China. The earlier work in cryptology was centered on messages that were expressed using alphanumeric symbols; hence encryption involved simple algorithms such as shifting characters within the string of the message in a defined manner, which is now known as shift cipher. We will also introduce the necessary mathematics of cryptography: integer and modular arithmetic, linear congruence, Euclidean and

Extended Euclidean algorithms, Fermat's theorem, and elliptic curves. We will specify useful notations in context.

Take the set of integers:

$$Z = \{............, -3, -2, -1, 0, 1, 2, 3, ...\}$$

For any integers *a* and *n*, we say that *n* divides *a* if the remainder is zero after the division, or else we write:

$$a = q \bullet n + r \quad q: \text{quotient}, \ r: \text{remainder}$$

The Euclidean Algorithm

Given two positive integers, *a* and *b*, find the greatest common divisors of *a* and *b*. Let *d* be the greatest common divisors *(gcd)* of *a* and *b*, then,

$$d = \gcd(a,b)$$

Use the following example:

$$\gcd(36,10) = \gcd(10,6) = \gcd(6,4) = \gcd(4,2) = \gcd(2,0) = 2$$

Hence:

$$\gcd(36,10) = 2$$

The Extended Euclidean Algorithm

Let *a* and *b* be two positive integers, then

$$d = \gcd(a, b) = ax + by$$

Use the following example:

$$\begin{aligned} \gcd(540,168) &= \gcd(168,36) = \gcd(36,24) \\ &= \gcd(24,12) = \gcd(12,0) = 12 \end{aligned}$$

$$540 = 3(168) + 36 \qquad 36 = 540 - 3(168)$$
$$168 = 4(36) + 24 \qquad 24 = 168 - 4(36)$$
$$36 = 1(24) + 12 \qquad 12 = 36 - 1(24)$$
$$\begin{aligned} 12 &= 540 - 3(168) - 168 + 4(36) \\ &= 540 - 4(168) + 4(36) \\ &= 540 - 4(168) + 4(540) - 12(168) \\ &= 5(540) - 16(168) \end{aligned}$$

Therefore:

$$x = 5 \quad \text{and} \quad y = -16$$

Hence:

$$12 = (5)540 - (16)168$$

Modular Arithmetic

For a given integer *a*, positive integer *m*, and the remainder *r*,

$$r = a \ (\text{mod } m)$$

Consider examples:

$$2 = 27 \bmod 5$$
$$10 = -18 \bmod 14$$

{divide −18 by 14 leaves −4 as a remainder, then add 14 to −4 so that (−4 + 14) = 10 so the remainder is nonnegative}

A set of *residues* is a set consisting of remainders obtained by dividing positive integers by a chosen positive number *m* (modulus).

$$Z_m = a \ (\text{mod } m) = \{0, 1, 2, 3, ..., m-1\}$$

Take $m = 7$, then

$$Z_7 = \{0, 1, 2, 3, 4, 5, 6\}$$

Congruence

In arithmetic we normally use the relational operator, equal (=), to express that the pair of numbers are equal to each other, which is a binary operation. In cryptography we use *congruence* to express that the residue is the same for a set of integers divided by a positive integer. This essentially groups the positive integers into equivalence classes. Let's look at some examples:

$$2 \equiv 2 \bmod 10; \ 2 \equiv 12 \bmod 10; 2 \equiv 22 \bmod 10$$

Hence we say that the set {2, 12, 22} are congruent mod 10.

Residue Class

A residue class is a set of integers congruent mod *m*, where *m* is a positive integer.

Take $m = 7$:

$$[0] = \{.........., -21, -14, -7, 0, 7, 14, 21, ...\}$$
$$[1] = \{.........., -20, -3, -6, 1, 8, 15, 22, ...\}$$
$$[2] = \{..........., -19, -12, -5, 2, 9, 16, 23, ...\}$$
$$[3] = \{..........., -18, -11, -4, 3, 10, 17, 24, ...\}$$
$$[4] = \{..........., -17, -10, -3, 4, 11, 18, 25, ...\}$$
$$[5] = \{............, -16, -9, -2, 5, 12, 19, 26, ...\}$$
$$[6] = \{............, -15, -8, -1, 6, 13, 20, 27, ...\}$$

Some more useful operations defined in $\mathbf{Z}_m$:

$$(a+b)\text{mod } m = \{(a \text{ mod } m) + (b \text{ mod } m)\}\text{mod } m$$
$$(a-b)\text{mod } m = \{(a \text{ mod } m) - (b \text{ mod } m)\}\text{mod } m$$
$$(a*b)\text{mod } m = \{(a \text{ mod } m) * (b \text{ mod } m)\}\text{mod } m$$

$$10^n(\text{mod } x) = \langle 10 \text{ mod } x\rangle^n \text{mod } m$$

Inverses

In everyday arithmetic, it is quite simple to find the inverse of a given integer if the binary operation is either additive or multiplicative, but such is not the case with modular arithmetic.

We will begin with the additive inverse of two numbers $a, b \in Z_m$

$$(a+b) \equiv 0 \text{ (mod m)}$$

That is, the additive inverse of a is $b = (m - a)$.

Given

$$a = 4, \quad \text{and} \quad m = 10$$

then:

$$b = m - a = 10 - 4 = 6$$

Verify:

$$4 + 6 \equiv 0 \text{ (mod 10)}$$

Similarly, the multiplicative inverse of two integers $a, b \in Z_m$ if

$$a * b \equiv 1 \text{ (mod m)}$$

a has a multiplicative inverse $b \in Z_m$ if and only if

$$\gcd(m, a) = 1$$

in which case (m, a) are relative prime.

We remind the reader that a prime number is any number greater than 1 that is divisible (with a remainder 0) only by itself and 1. For example, {2, 3, 5, 7, 11, 13,...} are prime numbers, and we quote the following theorem for the reader.

Fundamental Theorem of Arithmetic

Each positive number is either a prime number or a composite number, in which case it can be expressed as a product of prime numbers.

Let's consider a set of integers mod 10 to find the multiplicative inverse of the numbers in the set:

$$Z_{10} = \{0, 1, 2, 3, 4, 5, 6, 7, 8, 9\}$$
$$(1*1)\text{mod } 10 = 1$$
$$(3*7)\text{mod } 10 = 1$$
$$(9*9)\text{mod } 10 = 1$$

then there are only three pairs (1,1); (3,7); and (9,9):

$$Z_{10*} = \{1, 3, 7, 9\}$$

The numbers {0, 2, 4, 5, 6, 8} have no multiplicative inverse.

Consider a set:

$$Z_6 = \{0, 1, 2, 3, 4, 5\}$$

Then,

$$Z_{6*} = \{1, 5\}$$

You will note that Z_{n*} is a subset of Z_n with unique multiplicative inverse.

Each member of Z_n has a unique additive inverse, whereas each member of Z_{n*} has a unique multiplicative inverse.

Congruence Relation Defined

The a is congruent to b (mod m) if m divides $(a - b)$, that is, the remainder is zero.

$$a \equiv b \text{ mod m}$$

Examples: $87 \equiv 27$ mod 4, $67 \equiv 1$ mod 6.

Next we quote three theorems:

Theorem 1: Suppose that $a \equiv c$ mod m and $b \equiv = d$ mod m, then

$$a + b \equiv c + d(\text{mod m})$$
$$a * b \equiv c * d(\text{mod m})$$

Theorem 2: Suppose $a*b \equiv a*c$ (mod m)

$$\text{and } \gcd(a, m) = 1$$
$$\text{then } b \equiv c \text{ (mod m)}$$

Theorem 3: Suppose $a*b \equiv a*c$ (mod m)

$$\text{and } d = \gcd(a, m)$$
$$\text{then } b \equiv c \text{ (mod m/d)}$$

Example to illustrate the use of the theorems just stated:

$$6 \equiv 36 \text{ (mod 10)}$$

then

$$3 \times 2 \equiv 3 \times 12 \text{ (mod 10)}$$

since

$$\gcd(3, 10) = 1$$

therefore,

$$2 \equiv 12 \text{ (mod 10)}$$

also

$$2 = \gcd(6, 10)$$

therefore,

$$1 \equiv 6 \pmod 5$$

Given,

$$14x \equiv 12 \pmod{18}$$

find x.

Since

$$\gcd(14,\ 18) = 2$$

therefore,

$$7x \equiv 6 \pmod 9$$

you will observe that,

$$\gcd(7,\ 9) = 1$$

therefore,

$$x \equiv 6(7^{-1}) \bmod 9$$

and the multiplicative inverse of 7^{-1} is 4, therefore,

$$x \equiv (6 * 4) \pmod 9 = 6$$

Substitution Cipher

Shift ciphers, also known as *additive ciphers*, are an example of a monoalphabetic character cipher in which each character is mapped to another character, and a repeated character maps to the same character irrespective of its position in the string. We give a simple example of an additive cipher, where the key is 3, and the algorithm is "add." We restrict the mapping to {0, 1, ..., 7} (see Table 37.1)—that is, we use mod 8. This is an example of finite domain and the range for mapping, so the inverse of the function can be determined easily from the ciphertext.

Observations:

- The domain of the function is $x = \{0,1,2,3,4,5,6,7\}$.
- The range of the function is $y = \{0,1,2,3,4,5,6,7\}$.
- The function is 1 to 1.
- The function is invertible.
- The inverse function is $x = (y - 3) \bmod 8$.

TABLE 37.1 Table of values for $y = (x + 3) \bmod 8$, given values of $x = \{0,1,... 7\}$.

X	0	1	2	3	4	5	6	7
y	3	4	5	6	7	0	1	2

The affine cipher has two operations, addition and multiplication, with two keys. Once again the arithmetic is mod m, where m is a chosen positive integer.

$$y = (kx + b) \bmod m$$

where k and b are chosen from integers {0, 1, 2, 3,.........., $(m - 1)$}, and x is the symbol to be encrypted.

The decryption is given as:

$$x = [(y - b) * k^{-1}] \bmod m$$

where

$$k^{-1}$$

is the multiplicative inverse of k in Z_{n^*}

$(—b)$ is the additive inverse in Z_n

Consider,

$$y = (5 * x + 3) \bmod 8$$

Then,

$$x = (y - 3)5 \bmod 8$$

In this case, the multiplicative inverse of 5 happens to be 5.

Monoalphabetic substitution ciphers are easily broken, since the key size is small (see Table 37.2).

$$Z_8 = \{0, 1, 2,\ 3, 4, 5, 6, 7, \}$$
$$Z_{8*} = \{1, 3, 5\}$$

Transposition Cipher

A transposition cipher changes the location of the character by a given set of rules known as *permutation*. A cyclic group defines the permutation with a single key to encrypt, and the same key is used to decrypt the ciphered message. Table 37.3 provides an illustration.

4. MODERN SYMMETRIC CIPHERS

Computers internally represent printable data in binary format as strings of zeros and ones. Therefore any data is

TABLE 37.2 Monoalphabetic Substitution Cipher.

X	0	1	2	3	4	5	6	7
y	3	0	5	2	7	4	1	6

TABLE 37.3 Transposition Cipher.

1	2	3	4	5
3	1	4	5	2

represented as a large block of zeros and ones. The processing speed of a computer is used to encrypt the block of zeros and ones. Securing all the data in one go would not be practical, nor would it secure the data; hence the scheme to treat data in chunks of blocks, leading to the concept of block ciphers.

The most common value of a block is 64, 128, 256, or 512 bits. You will observe that these values are powers of 2, since computers process data in binary representation using modular arithmetic with modulus 2. We need an algorithm and a key to encrypt the blocks of binary data such that the ciphered data is confusing and diffusing to the hacker. The algorithm is made public, whereas the key is kept secret from unauthorized users so that hackers could establish the robustness of the cipher by attempting to break the encrypted message. The logic of the block cipher is as follows:

- Each bit of ciphertext should depend on all bits of the key and all bits of the plaintext.
- There should be no evidence of statistical relationship between the plaintext and the ciphertext.

In essence, this is the goal of an encryption algorithm: Confuse the message so that there is no apparent relationship between the ciphertext and the plaintext. This is achieved by the substitution rule (S-boxes) and the key.

If changing one bit in the plaintext has a minimal effect on the encrypted text, it might be possible for the hacker to work backward from the encrypted text to the plaintext by changing the bits. Therefore a minimal change in the plaintext should lead to a maximum change in the ciphertext, resulting in spreading, which is known as *diffusion*. Permutation or P-boxes implement the diffusion.

The symmetric cipher consists of an algorithm and a key. The algorithm is made public, whereas the key is kept secret and is known only to the parties that are exchanging messages. Of course, this does create a huge problem, since every pair that is going to exchange messages will need a secret key, growing indefinitely in number as the number of pairs increases. We also would need a mechanism by which to manage the secret keys. We will address these issues later on.

The symmetric algorithm would consist of finite rounds of S-boxes and P-boxes. Once the plaintext is encrypted using the algorithm and the key, it would need to be decrypted using the same algorithm and key. The decryption algorithm and the key would need to work backward in some sense to revert the encrypted message to its original message.

So you begin to see that the algorithm must consist of a finite number of combinations of S-boxes and P-boxes; encryption is mapping from message space (domain) to another message space (range), that is, mapping should be a closed operation, a "necessary" condition on the encryption algorithm. This implies that message strings get mapped to message strings, and of course these message strings belong to a set of messages. We are not concerned with the semantics of the message; we leave this to the message sender and receiver. The S-boxes and P-boxes would define a set of operations on the messages or bits that represent the string of messages. Therefore we require that this set of operations should also be able to undo the encryption, that is, mapping must be invertible in the mathematical sense. Hence the set of operations must have definite relationships among them, resulting in some structural and logical connection. In mathematics an example of this is an algebraic structure such as group, ring, and field, which we explore in the next section.

S-Box

The reader should note that an S-box can have a 3-bit input binary string, and its output may be a 2-bit. The S-box may use a key or be keyless. Let *S(x)* be the linear function computed by the following function [1]:

$$S(x_1x_2x_3) = [(1 + x_1 + x_2 + x_3 + x_1 \bullet x_2)\mathrm{mod}2]$$
$$[(1 + x_3 + x_1 \bullet x_3 + x_1 \bullet x_2)\mathrm{mod}2]$$

Such a function is referred to as an *S-box*. For a given 4-bit block of plaintext $x_1x_2x_3x_4$ and the 3-bit key, $k_1k_2k_3$, let

$$E(x_1x_2x_3x_4,\ k_1k_2k_3) = x_1x_2(x_3x_4 \oplus S(x_2x_1x_2 \oplus k_1k_2k_3))$$

where $\oplus$ represents exclusive OR

Given ciphertext, $y_1y_2y_3y_4$ computed with E and the key, $k_1k_2k_3$, compute

$$D(y_1y_2y_3y_4,\ k_1k_2k_3) = (y_1y_2 \oplus S(y_4y_3y_4 \oplus k_1k_2k_3))y_3y_4$$

S-boxes are classified as linear if the number of output bits is the same as the number of input bits, and they're nonlinear if the number of output bits is different from the number of input bits. Furthermore, S-boxes can be invertible or noninvertible.

P-Boxes

A *P-box* (permutation box) will permute the bits per specification. There are three different types of P-boxes, as shown in Tables 37.4, 37.5, and 37.6.

In the compression P-box, inputs 2 and 4 are blocked.

The expansion P-box maps elements 1, 2, and 3 only.

Let's consider a permutation group with the mapping defined, as shown in Table 37.7.

This group is a cyclic group with elements:

$$G = (e,\ a,\ a^2,\ a^3,\ a^4,\ a^5,\ a^6)$$

The identity mapping is given by $a^7 = e$. The inverse element is a^{-1}.

Table 37.7 shows a permutation of an 8-bit string (11110010).

Product Ciphers

Modern block ciphers are divided into two categories. The first category of the cipher uses both invertible and noninvertible components. A Feistel cipher belongs to the first category, and DES is a good example of a Feistel cipher. This cipher uses the combination of S-boxes and P-boxes with compression and expansion (noninvertible).

The second category of cipher only uses invertible components, and Advanced Encryption Standard (AES) is an example of a non-Feistel cipher. AES uses S-boxes with an equal number of inputs and outputs and a straight P-box that is invertible.

Alternation of substitutions and transpositions of appropriate forms when applied to a block of plaintext can have the effect of obscuring statistical relationships between the plaintext and the ciphertext and between the key and the ciphertext (diffusion and confusion).

5. ALGEBRAIC STRUCTURE

Modern encryption algorithms such as DES, AES, RSA, and ElGamal, to name a few, are based on algebraic structures such as group theory and field theory as well as number theory. We will begin with a set S, with a finite number of elements and a binary operation (*) defined between any two elements of the set:

$$* : S \times S \rightarrow S$$

that is, if a and $b \in S$, then $a * b \in S$. This is important because it implies that the set is closed under the binary operation. We have seen that the message space is finite, and we want to make sure that any algebraic operation on the message space satisfies the closure property. Hence, we want to treat the message space as a finite set of elements. We remind the reader that messages that get encrypted must be finally decrypted by the received party, so the encryption algorithm must run in polynomial time; furthermore, the algorithm must have the property that it be reversible, to recover the original message. The goal of encryption is to confuse and diffuse the hacker to make it almost impossible for the hacker to break the encrypted message. Therefore, encryption must consist of finite number substitutions and transpositions. The algebraic structure *classical group* facilitates the coding of encryption algorithms.

Next we give some relevant definitions and examples before we proceed to introduce the essential concept of a Galois field, which is central to formulation of a Rijndael algorithm used in the Advanced Encryption Standard.

Definition Group

A definition group (G, •) is a finite set G together with an operation • satisfying the following conditions [2]:

- Closure: $\forall a, b \in \mathrm{G}$, then $(a \bullet b) \in \mathrm{G}$
- Associativity: $\forall a, b, c \in \mathrm{G}$, then $a \bullet (b \bullet c) = (a \bullet b) \bullet c$
- Existence of identity: $\exists a$ unique element $e \in \mathrm{G}$ such that $\forall a \in \mathrm{G}$: $a \bullet e = e \bullet a$
- $\forall\ a \in \mathrm{G}: \forall a^{-1}\mathrm{G}$: $a^{-1}a = a^{-1} \bullet a = e$

Definitions of Finite and Infinite Groups (Order of a Group)

A group G is said to be finite if the number of elements in the set G is finite; otherwise the group is infinite.

Definition Abelian Group

A group G is abelian if for all $a, b \in G$, $a \bullet b = b \bullet a$

The reader should note that in a group, the elements in the set do not have to be numbers or objects; they can be mappings, functions, or rules.

Examples of a Group

The set of integers Z is a group under addition $(+)$, that is, $(Z, +)$ is a group with identity $e = 0$, and inverse of an element a is $(-a)$. This is an additive abelian group, but infinite.

Nonzero elements of Q (rationale), R (reals), and C (complex) form a group under multiplication, with the identity element $e = 1$, and a^{-1} being the multiplicative inverse.

For any $n \geq 1$, the set of integers modulo n forms a finite additive group of n elements.

$G = < Z_n, + >$ is an abelian group.

The set of Z_{n*} with multiplication operator, $G = < Z_{n*}, x >$ is also an abelian group.

The set Z_{n*}, is a subset of Z_n and includes only integers in Z_n that have a unique multiplicative inverse.

$$Z_{13} = \{0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12\}$$
$$Z_{13*} = \{1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12\}$$

Definition: Subgroup

A subgroup of a group G is a non empty subset H of G, which itself is a group under the same operations as that of G. We denote that H is a subgroup of G as $H \subseteq G$, and $H \subset G$ is a proper subgroup of G if the set $H \neq G$ [2]:

Examples of subgroups:

Under addition, $Z \subseteq Q \subseteq R \subseteq C$.

$H = < Z_{10}, + >$ is a proper subgroup of $G = < Z_{12}, + >$

Definition: Cyclic Group

A group G is said to be cyclic if there exists an element $a \in G$ such that for any $b \in G$, and $i \geq 0$, $b = a^i$. Element a is called a generator of G.

The group $G = < Z_{10*}, x >$ is a cyclic group with generators $g = 3$ and $g = 7$.

$$Z_{10*} = \{1, 3, 7, 9\}$$

The group $G = < Z_6, + >$ is a cyclic group with generators g = 1 and g = 5.

$$Z_6 = \{0, 1, 2, 3, 4, 5\}$$

Rings

Let R be a non-empty set with two binary operations addition $(+)$ and multiplication $(*)$. Then R is called a *ring* if the following axioms are met:

- Under addition, R is an abelian group with zero as the additive identity.
- Under multiplication, R satisfies the closure, the associativity, and the identity axiom; 1 is the multiplicative identity, and that $1 \neq 0$.
- For every a and b that belongs to R, $a \bullet b = b \bullet a$.
- For every a, b, and c that belongs to R, then $a \bullet (b + c) = a \bullet b + a \bullet c$.

Examples

Z, Q, R, and C are all rings under addition and multiplication. For any $n > 0$, Z_n is a ring under addition and multiplication modulo n with 0 as identity under addition, 1 under multiplication.

Definition: Field

If the nonzero elements of a ring form a group under multiplication, the ring is called a *field*.

Examples

Q, R, and C are all fields under addition and multiplication, with 0 and 1 as identity under addition and multiplication.

Note: Z under integer addition and multiplication is not a field because any nonzero element does not have a multiplicative inverse in Z.

Finite Fields $GF(2^n)$

Construction of finite fields and computations in finite fields are based on polynomial computations. Finite fields play a significant role in cryptography and cryptographic protocols such as the Diffie and Hellman key exchange protocol, ElGamal cryptosystems, and AES.

For a prime number p, the quotient Z/p (or F_p) is a finite field with p number of elements. For any positive integer q, $GF(q) = F_q$. We define A to be algebraic structure such as a ring, group, or field.

Definition: A polynomial over A is an expression of the form

$$f(x) = \sum_{i=0}^{n} a_i x^n$$

where n is a nonnegative integer, the coefficient $a_i \in A$, $0 \le i \le n$, and $x \notin A$ [2].

Definition: A polynomial $f \in A[x]$ is said to be irreducible in $A[x]$ if f has a positive degree and $f = gh$ for some $g, h \in A[x]$ implies that either g or h is a constant polynomial [2].

The reader should be aware that a given polynomial can be reducible over one structure but irreducible over another.

Definition: *Let* f, g, q, and $r \in A[x]$ with $g \neq 0$. Then we say that r is a *remainder* of f divided by g:

$$r \equiv f(\text{mod } g)$$

The set of remainders of all the polynomials in $A[x]$ (mod g) denoted as $A[x]_g$.

Theorem: Let F be a field and f be a nonzero polynomial in $F[x]$. Then $F[x]_f$ is a ring and is a field if f is irreducible over F.

Theorem: Let F be a field of p elements, and f be an irreducible polynomial over F. Then the number of elements in the field $F[x]f$ is p^n[2].

For every prime p and every positive integer n there exists a finite field of p^n number of elements.

For any prime number p, Z_p is a finite field under addition and multiplication modulo p with 0 and 1 as the identity under addition and multiplication.

Z_p is an additive ring and the nonzero elements of Z_p, denoted by Z_{p*}, forms a multiplicative group.

Galois field, $GF(p^n)$ is a finite field with number of elements p^n, where p is a prime number and n is a positive integer.

Example: Integer representation of a finite field (Rijndael) element.

Polynomial $f(x) = x^8 + x^4 + x^3 + x + 1$ is irreducible over F_2.

The set of all polynomials(mod f) over F_2 forms a field of 2^8 elements; they are all polynomials over F_2 of degree less than 8. So any element in the field $F_2[x]_f$

$$b_7x^7 + b_6x^6 + b_5x^5 + b_4x^4 + b_3x^3 + b_2x^2 + b_1x^1 + b_0$$

where $b_7, b_6, b_5, b_4, b_3, b_2, b_1, b_0 \in F_2$ thus any element in this field can represent an 8-bit binary number.

We often use F_{2^8} field with 256 elements because there exists an isomorphism between Rijndael and F_{2^8}.

Data inside a computer is organized in bytes (8 bits) and is processed using Boolean logic, that is, bits are manipulated using binary operations addition and multiplication. These binary operations are implemented using the logical operator XOR, or in the language of finite fields, *GF(2)*. Since the extended ASCII defines 8 bits per byte, an 8-bit byte has a natural representation using a polynomial of degree 8. Polynomial addition would be mod 2, and multiplication would be mod polynomial degree 8. Of course this polynomial degree 8 would have to be irreducible. Hence the Galois field $GF(2^8)$ would be the most natural tool to implement the encryption algorithm. Furthermore, this would provide a close algebraic formulation.

Consider polynomials over $GF(2)$ with $p = 2$ and $n = 1$.

$$1,\ x,\ x+1,\ x^2+x+1,\ x^2+1,\ x^3+1$$

For polynomials with negative coefficients, -1 is the same as $+1$ in $GF(2)$. Obviously, the number of such polynomials is infinite. Algebraic operations of addition and multiplication in which the coefficients are added and multiplied according to the rules that apply to $GF(2)$ are sets of polynomials that form a ring.

Modular Polynomial Arithmetic Over GF(2)

The Galois field $GF(2^3)$: Construct this field with eight elements that can be represented by polynomials of the form

$$ax^2 + bx + c \text{ where } a, b, c \in GF(2) = \{0,\ 1\}$$

Two choices for a, b, c give $2 \times 2 \times 2 = 8$ polynomials of the form

$$ax^2 + bx + c \in GF_2[x]$$

What is our choice of the irreducible polynomials for this field?

$$(x^3+x^2+x+1),\ (x^3+x^2+1),\ (x^3+x^2+x),$$
$$(x^3+x+1),\ (x^3+x^2)$$

These two polynomials have no factors: (x^3+x^2+1), (x^3+x+1)

So we choose polynomial (x^3+x+1). Hence all polynomial arithmetic multiplication and division is carried out with respect to (x^3+x+1).

The eight polynomials that belong to $GF(2^3)$:

$$\{0,\ 1,\ x,\ x^2,\ 1+x,\ 1+x^2,\ x+x^2,\ 1+x+x^2\}$$

You will observe that GF(8) = {0,1,2,3,4,5,6,7} is not a field, since every element (excluding zero) does not have a multiplicative inverse such as {2, 4, 6} (mod 8) [2].

Using a Generator to Represent the Elements of $GF(2^n)$

It is particularly convenient to represent the elements of a Galois field with the help of a generator element. If α, is a generator element, then every element of $GF(2^n)$, except for the 0 element, can be written as some power of α. A generator is obtained from the irreducible polynomial

that was used to construct the finite field. If $f(\alpha)$ is the irreducible polynomial used, then α, is that element that satisfies the equation $f(\alpha) = 0$. You do not actually solve this equation for its roots, since an irreducible polynomial cannot have actual roots in the field GF(2).

Consider the case of $GF(2^3)$, defined with the irreducible polynomial $x^3 + x + 1$. The generator α, is that element that satisfies $\alpha^3 + \alpha + 1 = 0$. Suppose α is a root in $GF(2^3)$ of the polynomial $p(x) = 1 + x + x^3$, that is, $p(\alpha) = 0$, then

$$\alpha^3 = -\alpha - 1 \ (\text{mod } 2) = \alpha + 1$$
$$\alpha^4 = \alpha(\alpha + 1) = \alpha^2 + \alpha$$
$$\alpha^5 = \alpha^4 \bullet \alpha = (\alpha^2 + \alpha)\alpha = \alpha^3 + \alpha^2 = (\alpha^2 + \alpha + 1)$$
$$\alpha^6 = \alpha^5 \bullet \alpha = \alpha \bullet (\alpha^2 + \alpha + 1) = (\alpha^2 + 1)$$
$$\alpha^7 = (\alpha^2 + 1) \bullet \alpha = (2\alpha + 1)$$

All powers of α generate nonzero elements of GF_8. The polynomials of $GF(2^3)$ represent bit strings, as shown in Table 37.8.

We now consider all polynomials defined over $GF(2)$, modulo the irreducible polynomial $x^3 + x + 1$. When an algebraic operation (polynomial multiplication) results in a polynomial whose degree equals or exceeds that of the irreducible polynomial, we will take for our result the remainder modulo the irreducible polynomial. For example,

$$\begin{aligned} &(x^2 + x + 1) * (x^2 + 1) \text{ mod } (x^3 + x + 1) \\ &= (x^4 + x^3 + x^2) + (x^2 + x + 1) \text{ mod } (x^3 + x + 1) \\ &= (x^4 + x^3 + x + 1) \text{ mod } (x^3 + x + 1) \\ &= -x^2 + x \\ &= x^2 + x \end{aligned}$$

Recall that $1 + 1 = 0$ in GF(2). With multiplications modulo $(x^3 + x + 1)$, we have only the following eight polynomials in the set of polynomials over GF(2):

$$\{0,\ 1,\ x,\ x+1,\ x^2,\ x^2+1,\ x^2+x,\ x^2+x+1\}$$

We refer to this set as $GF(2^3)$, where the power of 2 is the degree of the modulus polynomial. The eight elements of Z_8 are to be integers modulo 8. Similarly, $GF(2^3)$ maps all the polynomials over GF(2) to the eight polynomials shown. But you will note the crucial difference between $GF(2^3)$ and 2^3: $GF(2^3)$ is a field, whereas Z_8 is *not* [2].

TABLE 37.8 The Polynomials of CF(2^3).

Polynomial	Bit String
0	000
1	001
x	010
$x+1$	011
X^2	100
x^2+1	101
X^2+X	110
x^2+x+1	111

$GF(2^3)$ is a Finite Field

We know that $GF(2^3)$ is an abelian group because the operation of polynomial addition satisfies all the requirements of a group operator and because polynomial addition is commutative. $GF(2^3)$ is also a commutative ring because polynomial multiplication is a distributive over polynomial addition. $GF(2^3)$ is a finite field because it is a finite set and because it contains a unique multiplicative inverse for every nonzero element.

$GF(2^n)$ is a finite field for every n. To find all the polynomials in $GF(2^n)$, we need an irreducible polynomial of degree n. AES arithmetic is based on $GF(2^8)$. It uses the following irreducible polynomial:

$$f(x) = x^8 + x^4 + x^3 + x + 1$$

The finite field $GF(2^8)$ used by AES obviously contains 256 distinct polynomials over GF(2). In general, GF(p^n) is a finite field for any prime p. The elements of GF(p^n) are polynomials over GF(p) (which is the same as the set of residues Z_p).

Next we show how the multiplicative inverse of a polynomial is calculated using the Extended Euclidean algorithm:

$$\text{Multiplicative inverse of } (x^2 + x + 1)$$
$$\text{in } F_2[x]/(x^4 + x + 1) \text{ is } (x^2 + x)$$
$$(x^2 + x)\,(x^2 + x + 1) = 1 \text{ mod } (x^4 + x + 1)$$
$$\text{Multiplicative inverse of } (x^6 + x + 1)$$
$$\text{in } F_2[x]/(x^8 + x^4 + x^3 + x + 1)$$
$$\text{is } (x^6 + x^5 + x^2 + x + 1)$$
$$(x^6 + x + 1)\,(x^6 + x^5 + x^2 + x + 1) = 1$$
$$\text{mod } (x^8 + x^4 + x^3x + 1)[2,\ 3]$$

6. THE INTERNAL FUNCTIONS OF RIJNDAEL IN AES IMPLEMENTATION

Rijndael is a block cipher. The messages are broken into blocks of a predetermined length, and each block is encrypted independently of the others. Rijndael operates on blocks that are 128-bits in length. There are actually three variants of the Rijndael cipher, each of which uses a different key length. The permissible key lengths are 128, 192, and 256 bits. The details of Rijndael may be found in Bennett and Gilles (1984), but we give an overview here [2,3].

Mathematical Preliminaries

Within a block, the fundamental unit operated on is a byte, that is, 8 bits. Bytes can be interpreted in two different ways. A byte is given in terms of its bits as $b_7b_6b_5b_4b_3b_2b_1b_0$. We may think of each bit as an element in GF(2), the finite field of two elements (mod 2). First, we may think of a byte as a vector, $b_7b_6b_5b_4b_3b_2b_1b_0$ in $GF(2^8)$. Second, we may think of a byte as an element of $GF(2^8)$, in the following way: Consider the polynomial ring GF(2)[*X*]. We may mod out by any polynomial to produce a factor ring. If this polynomial is irreducible and of degree *n*, the resulting factor ring is isomorphic to $GF(2^n)$. In Rijndael, we mod out by the irreducible polynomial X8 + X4 + X3 + X + 1 and so obtain a representation for $GF(2^8)$. The Rijndael algorithm deals with five units of data in the encryption scheme:

- Bit: A binary digit with a value of 0 or 1
- Byte: A group of 8 bits
- Word: A group of 32 bits
- Block: A block in AES is defined to be 128, 192 or 256 bits
- State: The data block is known as a *state*, and it is made up of a 4×4 matrix of 16 bytes (128 bits)

State

For our discussion purposes, we will consider a data block of 128 bits with a *ky* size of 128 bits. The state is 128 bits long. We think of the state as divided into 16 bytes, a_{ij} where $0 \le i, j \le 3$. We think of these 16 bytes as an array, or matrix, with 4 rows and 4 columns, such that a_{00} is the first byte, b_0 and so on (see Figure 37.1).

AES uses several rounds (10, 12, or 14) of transformations, beginning with a 128-bit block. A round is made up of four parts: S-box, permutation, mixing, and subkey addition. We discuss each part here [2,3].

The S-Box (SubByte)

S-boxes, or substitution boxes, are common in block ciphers. These are 1-to-l and onto functions, and therefore an inverse exists. Furthermore, these maps are nonlinear to make them immune to linear and differential cryptoanalysis. The S-box is the same in every round, and it acts independently on each byte. Each byte belongs to $GF(2^8)$ domain with 256 elements. For a given byte we compute the inverse of that byte in the $GF(2^8)$ field. This sends a byte x to x^{-1} if x is nonzero and sends it to 0 if it is zero. This defines a nonlinear transformation, as shown in Table 37.9.

$$\begin{bmatrix} a_{00} = b_0 & a_{01} = b_4 & a_{02} = b_8 & a_{03} = b_{12} \\ a_{10} = b_1 & a_{11} = b_5 & a_{12} = b_9 & a_{13} = b_{13} \\ a_{20} = b_2 & a_{21} = b_6 & a_{22} = b_{10} & a_{23} = b_{14} \\ a_{30} = b_3 & a_{31} = b_7 & a_{32} = b_{11} & a_{33} = b_{15} \end{bmatrix}$$

FIGURE 37.1 State.

Next we apply an affine (over GF(2)) transformation. Think of the byte x as a vector in $GF(2^8)$. Consider the invertible matrix A, as shown in Figure 37.2.

The structure of matrix A is relatively simple, successively shifting the prior row by 1. If we define the vector $v \in GF(2^8)$ to be (1, 1, 0, 0, 0, 1, 1, 0), then the second half of the S-box sends byte x to byte y through the affine transformation defined as:

$$y = A \cdot x^{-1} \oplus 1$$

Since the matrix A has an inverse, it is possible to recover x using the following procedure known as the InvSubByte:

$$x = [A^{-1}(y \oplus b)]^{-1}$$

We will demonstrate the action of an S-box by choosing an uppercase letter *S*, for which the hexadecimal representation is 53_{16} and binary representation is shown in Tables 37.10 and 37.11.

The letter *S* has a polynomial representation:

$$(x^6 + x^4 + x + 1)$$

The multiplicative inverse of $(x^6 + x^4 + x + 1)$ is $(x^7 + x^6 + x^3 + x)$, which is derived using the Extended Euclidean algorithm.

Next we multiply the multiplicative inverse x^{-1} with an invertible matrix A (see Figure 37.3) and add a column vector (b) and get the resulting column vector y (see Table 37.12). This corresponds to SubByte transformation and it is nonlinear [2].

$$y = A * x^{-1} + b$$

The column vector y represents a character ED_{16} in hexadecimal representation.

The reader should note that this transformation using the $GF(2^8)$ field is a pretty tedious computation, so instead we use an AES S-box lookup table (a 17×17 matrix expressed in hexadecimal) to replace the character with a replacement character. This corresponds to the SubByte transformation, and corresponding to the SubByte table there is an InvSubByte table that is the inverse of the SubByte table. The InvSubByte can be found in the references or is readily available on the Internet.

We will work with the following string: QUANTUMCRYPTOGOD, which is 16 bytes long, to illustrate AES (see Table 37.13). The state represents

TABLE 37.9 SubByte Transformation.

our string as a 4×4 matrix in the given arrangement using a hexadecimal representation of each byte (see Figure 37.4).

We apply SubByte transformation (see Figure 37.5) using the lookup table, which replaces each byte as defined in Table 37.13.

The next two rounds of ShiftRows and Mixing in the encryption lead to a diffusion process. The ShiftRow is a permutation.

ShiftRows

In the first step, we take the state and apply the following logic. The first row is kept as is. The second row is shifted left by one byte. The third row is shifted left by two bytes, and the last row is shifted left by three bytes. The resulting state is shown in Figure 37.6.

InvShiftRows in decryption shift bytes toward the right, similar to ShiftRows.

Mixing

The second step, the MixColumns transformation, mixes the columns. We interpret the bytes of each column as the coefficients of a polynomial in $GF(2^8)[x]/(x^4 + 1)$. Then we multiply each column by the polynomial '03'

$$\begin{bmatrix} 10001111 \\ 11000111 \\ 11100011 \\ 11110001 \\ 11111000 \\ 01111100 \\ 00111110 \\ 00011111 \end{bmatrix} \begin{pmatrix} 0 \\ 1 \\ 0 \\ 1 \\ 0 \\ 0 \\ 1 \\ 1 \end{pmatrix} + \begin{pmatrix} 1 \\ 1 \\ 0 \\ 0 \\ 0 \\ 1 \\ 1 \\ 0 \end{pmatrix} \textbf{(mod 2)} = \begin{pmatrix} 1 \\ 0 \\ 1 \\ 1 \\ 0 \\ 1 \\ 1 \\ 1 \end{pmatrix}$$

FIGURE 37.3 Multiplying the multiplicative inverse with an invertible matrix.

TABLE 37.12 Vectory.

1	1	1	0	1	1	0	1

x^3 + '02' x^2 + '01'x + '02'. Multiplication of the bytes is done in $GF(2^8)$ with mod $(x^4 + 1)$.

The mixing transformation remaps the four bytes to a new four bytes by changing the contents of the individual bytes (see Figure 37.7). The MixColumns transformation is applied to each column of the state, hence each column is multiplied by a constant matrix to obtain a new state, S'_{0i}.

$$S'_{0i} = 2\circ S_{0i} \oplus 3\circ S_{1i} \oplus S_{2i} \oplus S_{3i}$$

$$S'_{00} = 2\circ S_{00} \oplus 3\circ S_{10} \oplus S_{20} \oplus S_{30}$$

$$S_{20} \oplus S_{30} = 53 \oplus 1B$$

$$= (01010011) \oplus (00011011)$$

$$= (01001000)$$

$$2\circ S_{00} = (00000010)\circ(D1)$$

$$= (x)\circ(11010001)$$

$$= (x)\,(x^7 + x^6 + x^4 + 1)$$

$$= (x^8 + x^7 + x^5 + x)\mathrm{mod}(x^8 + x^4 + x^3 + x + 1)$$

$$= (x^7 + x^5 + x^4 + x^3 + 1)$$

$$= (10111001)$$

$$3\circ S_{10} = (00000011)\,(FC)$$

$$= (00000011)(11111100)$$

$$= \{(x + 1)\,(x^7 + x^6 + x^5 + x^4 + x^3 + x^2)\}$$

$$\mathrm{mod}(x^8 + x^4 + x^3 + x + 1)$$

$$= (00011111)$$

$$S'_{00} = (10111001) \oplus (00011111) \oplus (01001000)$$

$$= (11101110) = 0 \times EE$$

Subkey Addition

From the original key, we produce a succession of 128-bit keys by means of a key schedule. Let's recap that a word is a group of 32 bits. A 128-bit key is labeled as shown in Table 37.14.

word $W_0 = (k_0k_1k_2k_3)$ word $W_1 = (k_4k_5k_6k_7)$
word $W_2 = (k_8k_9k_{10}k_{11})$ word $W_3 = (k_{12}k_{13}k_{14}k_{15})$

which is then written as a 4×4 matrix (see Figure 37.8), where W_0 is the first column, W_1 is the second column, W_2 is the third column, and W_3 is the fourth column.

AES uses a process called *key expansion* that creates $(10 + 1)$ round keys from the given cipher key. We start with four words and end with 44 words—four word per round key. Thus

$$(W_{0,\ldots\ldots\ldots\ldots\ldots,}W_{42,}W_{43})$$

The algorithm to generate 10 round keys is as follows:
The initial cipher key consists of words: $W_0W_1W_2W_3$
The other 10 round keys are made using the following logic:
If (j mod 4)$\neq$0

$$W_j = W_{j-1} \oplus W_{j-4}$$

else

$$W_j = Z \oplus W_{j-4}$$

where $Z = \mathrm{SubWord}(\mathrm{RotWord}(W_{j-1}) \oplus \mathrm{RCon}_{j/4}$.

RotWord (rotate word) takes a word as an array of four bytes and shifts each byte to the left with wrapping. SubWord (substitute word) uses the SubByte lookup table to substitute the byte in the word [2,3]. RCon (round constants) is a four-byte value in which the rightmost three bytes are set to zero [2,3].

Let's work through an example, as shown in Figure 37.9.

Key: 2B 7E 15 16 28 AE D2 A6 AB F7 15 88 09 CF 4F 3C

W_0 = 2B 7E 15 16 W_1 = 28 AE D2 A6 W_2 = AB F7 15 88 W_3 = 09 CF 4F 3C

Compute W_4:

$$W_4 = Z \oplus W_0$$

$$\mathrm{RotWord}(W_3) = \mathrm{RotWord}(09\ CF\ 4F\ 3C)$$

$$= (CF4F3C09)$$

$$\mathrm{SubWord}(CF\ 4F\ 3C\ 09) = (8A\ 84\ EB\ 01)$$

$$Z = (8A\ 84\ EB\ 01) \oplus (01\ 00\ 00\ 00)_{16} = 8B\ 84\ EB\ 01$$

Hence,

$$W_4 = (8B\ 84\ EB\ 01) \oplus (2B\ 7E1516) = A0\ FA\ FE\ 17$$

FIGURE 37.7 Mixing transformation.

Putting it Together

Put the input into the state: XOR is the state with the 0-th round key. We start with this because any actions before the first (or after the last) use of the key are pointless, since they are publicly known and so can be undone by an attacker. Then apply 10 of the preceding rounds, skipping the column mixing on the last round (but proceeding to a final key XOR in that round). The resulting state is the ciphertext. We use the following labels to describe the encryption procedure (see Table 37.15):

Key 1 : K1 : $W_0W_1W_2W_3$
Key 2 : K2 : $W_4W_5W_6W_7$

Key 11: K11 : $W_{40}W_{41}W_{42}W_{43}$
The Initial State (IS) is the plaintext
The Output State (OSI)
SubByte (SB), ShiftRows (SR), MixColumns (MC)
Round
Pre-round PlainText $\oplus$ K1 $= = = = \rightarrow$OSI

Next we cycle through the decryption procedure:
InvSubByte (ISB), InvShiftRows (ISR), InvMix Columns (IMC)

Round

AES is a non-Feistel cipher, hence each set of transformations such as SubByte, ShiftRows, and MixColumns are invertible so that the decryption must consist of steps to recover the plaintext. You will observe that the round keys are used in the reverse order (see Table 37.16).

7. USE OF MODERN BLOCK CIPHERS

DES and AES are designed to encrypt and decrypt data blocks of fixed size. Most practical examples have data blocks of fewer than 64 bits or greater than 128 bits, and to address this issue currently, five different modes of operation have been set up. These five modes of operation are known as Electronic Code Book (ECB), Cipher-Block Chaining (CBC), Output Feedback (OFB), Cipher Feedback (CFB), and Counter (CTR) modes.

The Electronic Code Book (ECB)

In this mode, the message is split into blocks, and the blocks are sequentially encrypted. This mode is vulnerable to attack using the frequency analysis, the same sort used in simple substitution. Identical blocks would get encrypted to the same blocks, thus exposing the key [1].

Cipher-Block Chaining (CBC)

A logical operation is performed on the first block with what is known as an *initial vector* using the secret key so as to randomize the first block. The output of this step is logically combined with the second block and the key to

TABLE 37.14 Subkey Addition.

generate encrypted text, which is then used with the third block and so on [1].

8. PUBLIC-KEY CRYPTOGRAPHY

In this section we cover what is known as *asymmetric encryption*, which uses a pair of keys rather than one key, as used in symmetric encryption. This single-key encryption between the two parties requires that each party has its secret key, so that as the number of parties increases so does the number of keys. In addition, the distribution of the secret key becomes unmanageable as the number of keys increases. Of course, a longtime use of the same secret key between any pair would make it more vulnerable to cryptoanalysis attack. So, to deal with these inextricable problems, a key distribution facility was born. Symmetric encryption is considered more practical in dealing with vast amounts of data consisting of strings of zeros and ones. Yet another scheme was invented to secure data while in transition, using tools from a branch of mathematics known as number theory. To begin, let's review the necessary number theory concepts [2,3].

Review: Number Theory

Asymmetric-key encryption uses prime numbers, which are a subset of positive integers. Positive integers are all odd and even numbers, including the number 1, such that some of the numbers are composite, that is, products of numbers therein. This critical fact plays a significant role in generating keys. Next we will go through some statements of fact for the sake of completeness.

Coprimes

Two positive integers are said to be coprime or relatively prime if $\gcd(a, b) = 1$.

Cardinality of Primes

The number of primes is infinite. Given a number n, how many prime numbers are smaller than or equal to n? The answer to this question was discovered by Gauss and Lagrange as:

$$\{n/\ln(n) < \Pi\ (n) < \{n/\ln(n) - 1.08366\}$$

where $\Pi(n)$ is the number of primes smaller than or equal to n.

Check whether a given number 107 is a prime number. We take the square root of 107 to the nearest whole number, which is 10. Then count the number of primes less than 10, which are 2, 3, 5, 7. Next we check whether any one of these numbers will divide 107. In our example none of these numbers can divide 107, so 107 is a prime number.

Euler's Phi-Function $\phi(n)$: Euler's totient function finds the number of integers that are both smaller than n and coprime to n.

- $\phi(1) = 0$
- $\phi(p) = p - 1$ if p is a prime
- $\phi(m \times n) = \phi(n) \times \phi(m)$ if m and n are coprime
- $\phi(p^e) = p^e - p^{e-1}$ if p is a prime

Examples:

$\phi(2) = 1;\ \phi(3) = 2;\ \phi(4) = 2;\ \phi(5) = 4;\ \phi(6) = 2;\ \phi(7) = 6;\ \phi(8) = 4$

Factoring

The fundamental theorem of arithmetic states that every positive integer can be written as a product of prime numbers. There are a number of algorithms to factor large composite numbers.

Fermat's Little Theorem

In the 1970s, the creators of digital signatures and public-key cryptography realized that the framework for their research was already laid out in the body of work by Fermat and Euler. Generation of a key in public-key cryptography involves exponentiation modulo of a given modulus.

$$2^{13} \pmod{33} \equiv 2^{8+4+1} \equiv 25.16.2 \equiv 25.32 \equiv 8 \pmod{33}$$

$$6^{43} \pmod{13}$$

$$2^2 \equiv 4 \quad 3^2 \equiv 9$$

$$2^4 \equiv 4^2 \equiv 16 \equiv 33^4 \equiv 3$$

$$2^8 \equiv 3^2 \equiv 93^8 \equiv 9$$

$$2^{16} \equiv 9^2 \equiv 81 \equiv 33^{16} \equiv 3$$

$$2^{32} \equiv 3^2 \equiv 9 \pmod{13} \quad 3^{32} \equiv 9 \pmod{13}$$

Theorem. Let p be a prime number.

1. If a is coprime to p, then $a^{p-1} \equiv 1 \pmod p$
2. $a^p \equiv a \pmod p$ for any integer a

Examples:

$$43^{58} \equiv 1 \pmod{59}$$
$$86^{97} \equiv 86 \pmod{97}$$

Theorem: Let p and q be distinct primes.

1. If a is coprime to pq, then

$$a^{k(p-1)(q-1)} \equiv 1 \pmod{pq}, \text{k is any integer}$$

2. For any integer a,

$$a^{k(p-1)(q-1)+1} \equiv a \pmod{pq}, \text{ k is any positive integer}$$

Example:

$$62^{60} \equiv 62^{(7-1)-(11-1)} \equiv 1 \pmod{77}$$

Discrete Logarithm

Here we will deal with multiplicative group $G = \langle Z_{n*}x \rangle$. The order of a finite group is the number of elements in the group G. Let's take an example of a group,

$$G = \langle Z_{21*}, x \rangle$$

$$\phi(21) = \phi(3) \times \phi(7) = 2 \times 6 = 12$$

that is, 12 elements in the group, and each is coprime to 21.

$$\{1, 2, 4, 5, 8, 9, 10, 11, 13, 16, 17, 19, 20\}$$

The order of an element, ord(a) is the smallest integer i such that

$$a^i \equiv e \pmod{}$$

where $e = 1$.

Find the order of all elements in $G = \langle Z_{10*} x \rangle$
$$\phi(10) = \phi(2) \times \phi(5) = 1 \times 4 = 4$$
$$\{1, 3, 7, 9\}$$

Lagrange's theorem states that the order of an element divides the order of the group. In our example {1, 2, 4} each of them divide 4, therefore we need to check only these powers to find the order of the element.

$$1^1 \equiv 1 \ (\text{mod } 10) \rightarrow \text{ord}(1) = 1$$
$$3^1 \equiv 3 \ (\text{mod } 10); 3^2 \equiv 9(\text{mod } 10); 3^4 \equiv 1 \ (\text{mod } 10) \rightarrow \text{ord}(3) = 4$$
$$7^1 \equiv 7 \ (\text{mod } 10); 7^2 \equiv 9 \ (\text{mod } 10); 7^4 \equiv 1(\text{mod } 10) \rightarrow \text{ord}(7) = 4$$
$$9^1 \equiv 9 \ (\text{mod } 10); 9^2 \equiv 1 \ (\text{mod } 10) \rightarrow \text{ord}(9) = 2$$

If $a \in G = <Z_{n*}, x>$, then $a^{\phi(n)} = 1 \text{ mod n}$

Euler's theorem shows that the relationship $a^i \equiv 1$ (mod n) holds whenever the order (i) of an element equals ϕ(n).

Primitive Roots

In the multiplicative group, if $G = <Z_{n*}, x>$ when the order of an element is the same as $\phi(n)$, then that element is called the primitive root of the group. This property of primitive root is used in ElGamal cryptosystem.

$G = <Z_{8*}, x>$ has no primitive roots. The order of this group is $\phi(8) = 4$.

$$Z_{8*} = \{1, 3, 5, 7\}$$

1, 2, 4 each divide the order of the group, which is 4.

$$1^1 \equiv 1 \ (\text{mod } 8) \rightarrow \text{ord}(1) = 1$$
$$3^1 \equiv 3 \ (\text{mod } 8); \ 3^2 \equiv 1 \ (\text{mod } 8) \quad \rightarrow \text{ord}(3) = 2$$
$$5^1 \equiv 5 \ (\text{mod } 8); \ 5^2 \equiv 1 \ (\text{mod } 8) \quad \rightarrow \text{ord}(5) = 2$$
$$7^1 \equiv 7 \ (\text{mod } 8); \ 7^2 \equiv 1 \ (\text{mod } 8) \quad \rightarrow \text{ord}(7) = 2$$

In this example none of the elements has an order of 4, hence this group has no primitive roots. We will rearrange our data as shown in Table 37.17 [2, 3].

Let's take another example: $G = <Z_{7*}, x>$, then $\phi(7) = 6$, hence the order of the group is 6 with these members {1, 2, 3, 4, 5, 6}, which are all coprime to 7. We note that the order of each of these elements {1, 2, 3, 4, 5, 6} is the smallest integer i such that $a^i \equiv 1$ (mod 7). We note that the order of an element divides the order of the group. Thus the only numbers that divide 6 are {1, 2, 3, 6}:

A. $1^1 \equiv 1 \ (\text{mod } 7); \ 1^2 \equiv 1 \ (\text{mod } 7); \ 1^3 \equiv 1 \ (\text{mod } 7); \ 1^2 \equiv 1 \ (\text{mod } 7);$
$1^5 \equiv 1 \ (\text{mod } 7); \ 1^6 \equiv 1 \ (\text{mod } 7); \rightarrow \text{ord}(1) = 1$

B. $2^1 \equiv 2 \ (\text{mod } 7); \ 2^2 \equiv 4 \ (\text{mod } 7); \ 2^3 \equiv 1 \ (\text{mod } 7); \ 2^4 \equiv 2 \ (\text{mod } 7);$
$2^5 \equiv 4 \ (\text{mod } 7); \ 2^6 \equiv 1 \ (\text{mod } 7); \rightarrow \text{ord}(2) = 3$

C. $3^1 \equiv 3 \ (\text{mod } 7); \ 3^2 \equiv 2 \ (\text{mod } 7); \ 3^3 \equiv 6 \ (\text{mod } 7); \ 3^4 \equiv 4 \ (\text{mod } 7);$
$3^5 \equiv 5 \ (\text{mod } 7); \ 3^6 \equiv 1 \ (\text{mod } 7); \rightarrow \text{ord}(3) = 6$

D. $4^1 \equiv 4 \ (\text{mod } 7); \ 4^2 \equiv 2 \ (\text{mod } 7); \ 4^3 \equiv 1 \ (\text{mod } 7); \ 4^4 \equiv 4 \ (\text{mod } 7);$
$4^5 \equiv 2 \ (\text{mod } 7); \ 4^6 \equiv 1 \ (\text{mod } 7); \rightarrow \text{ord}(4) = 3$

E. $5^1 \equiv 5 \ (\text{mod } 7); \ 5^2 \equiv 4 \ (\text{mod } 7); \ 5^3 \equiv 6 \ (\text{mod } 7); \ 5^4 \equiv 2 \ (\text{mod } 7);$
$5^5 \equiv 3 \ (\text{mod } 7); \ 5^6 \equiv 1 \ (\text{mod } 7); \rightarrow \text{ord}(5) = 6$

F. $6^1 \equiv 6 \ (\text{mod } 7); \ 6^2 \equiv 1 \ (\text{mod } 7); \ 6^3 \equiv 6 \ (\text{mod } 7); \ 6^4 \equiv 1 \ (\text{mod } 7)$
$6^5 \equiv 6 \ (\text{mod } 7); \ 6^6 \equiv 1 \ (\text{mod } 7) \rightarrow \text{ord}(6) = 2$

Since the order of the elements {3, 5} is 6, which is the order of the group, therefore the primitive roots of the group are {3, 5}. In here the smallest integer $i = 6$, $\phi(7) = 6$.

Solve for x in each of the following:

$$5^x \equiv 6 \ (\text{mod } 7)$$

We can rewrite the above as:

$$x = \log_5 6 \ (\text{mod } 7)$$

Using the third term in E). we see that x must be equal to 3.

The group $G = <Z_{n*}, x>$ has primitive roots only if n is 2, 4, p^t, or $2p^t$, where p is an odd prime not including 2, and t is an integer.

If the group $G = <Z_{n*}, x>$ has any primitive roots, the number of primitive roots is $\phi(\phi(n))$.

Group $G = <Z_{n*}, x>$ has primitive roots, then it is cyclic, and each of its primitive roots is a generator of the whole group.

Group $G = <Z_{10*}, x>$ has two primitive roots because $\phi(10) = 4$, and $\phi(\phi(10)) = 2$. These two primitive roots are {3, 7}.

$$3^1 \text{ mod } 10 = 3 \ 3^2 \text{ mod } 10 = 9 \ 3^3 \text{ mod } 10 = 7 \ 3^4 \text{ mod } 10 = 1$$
$$7^1 \text{ mod } 10 = 7 \ 7^2 \text{ mod } 10 = 9 \ 7^3 \text{ mod } 10 = 3 \ 7^4 \text{ mod } 10 = 1$$

Group $G = <Z_{p*}, x>$ is always cyclic.

The group $G = <Z_{p*}, x>$ has the following properties:

- Its elements are from 1 to (p − 1) inclusive.
- It always has primitive roots.
- It is cyclic, and its elements can be generated using g where x is an integer from 1 to $\phi(n) = \text{p} - 1$.

TABLE 37.17 No Primitive Group.

	i = 1	i = 2	i = 3	i = 4	i = 5	i = 6	i = 7
a = 1	x:1	x:1	x:1	x:1	x:1	x:1	x:1
a = 3	x:3	x:1	x:3	x:1	x:3	x:1	x:3
a = 5	x:5	x:1	x:5	x:1	x:5	x:1	x:5
a = 7	x:7	x:1	x:7	x:1	x:7	x:1	x:7

- The primitive roots can be used as the base of a discrete logarithm.

Now that we have reviewed the necessary mathematical preliminaries, we will focus on the subject matter of asymmetric cryptography, which uses a public and a private key to encrypt and decrypt the plaintext. If Alice wants to send plaintext to Bob, she uses Bob's public key, which is advertised by Bob, to encrypt the plaintext and then send it to Bob via an unsecured channel. Bob decrypts the data using his private key, which is known to him only. Of course this would appear to be an ideal replacement for the asymmetric-key cipher, but it is much slower, since it has to encrypt each byte; hence it is useful in message authentication and communicating the secret key (see sidebar, "The RSA Cryptosystem").

9. CRYPTANALYSIS OF RSA

RSA algorithm relies that p and q, the distinct prime numbers, are kept secret, even though $m = p \times q$ is made public. So if n is an extremely large number, the problem reduces to find the factors that make up the number n, which is known as *the factorization attack*.

Factorization Attack

If the middleman, Eve, can factor n correctly, then she correctly guesses p, q, and $\phi(m)$. Reminding ourselves that the public key e is public, then Eve has to compute the multiplicative inverse of e:

$$d \equiv e^{-1} \pmod{m}$$

So if the modulus m is chosen to be 1024 bits long, it would take considerable time to break the RSA system unless an efficient factorization algorithm could be found [2,3] (see sidebars "Chosen-Ciphertext Attack" and "The e^{th} Roots Problem").

Discrete Logarithm Problem

Discrete logarithms are perhaps simplest to understand in the group Z_{p^*}, where p is the prime number. Let g be the generator of Z_{p^*}, then the discrete logarithm problem

The RSA Cryptosystem

Key generation algorithm:

1. Select two prime numbers p and q such that $p \neq q$.
2. Construct $m = p \times q$.
3. Set up a commutative ring $R = < Z_{\phi}, +, x >$ which is public since m is made public.
4. Set up a multiplicative group $G = < Zr_{(m)^*}, x >$ which is used to generate public and private keys. This group is hidden from the public since $\phi(m)$ is kept hidden.
   $\phi(m) = (p - 1)(q - 1)$
5. Choose an integer e such that, $1 < e < \phi(m)$ and e is coprime to $\phi(m)$.
6. Compute the secret exponent d such that, $1 < d < \phi$ (m) and that $ed \equiv 1 \pmod{\phi(m)}$.
7. The public key is "e" and the private key is "d." The value of p, q, and $\phi(m)$ are kept private.

Encryption:

1. Alice obtains Bob's public key (m, e).
2. The plaintext x is treated as a number to lie in the range $1 < x < m - 1$.
3. The ciphertext corresponding to x is $y = x^e \pmod{m}$.
4. Send the ciphertext y to Bob.

Decryption:	Example:
1. Bob uses his private key (m, d). 2. Compute the $x = y^d \pmod{m}$. Why RSA works:	1. Choose $p = 7$ and $q = 11$, then $m = p \times q = 7 \times 11 = 77$ $R = < Z_{77}, +, x >$ and $\phi(77) = \phi(7)\,\phi(11) = 6 \times 10 = 60$ 2. The corresponding multiplicative group $G = < Z_{60}^*, x >$. 3. Choose $e = 13$ and $d = 37$ from Z_{60}^* such that $e \times d \equiv 1 \pmod{60}$. Plaintext = 5 $y = x^e \pmod{m} = 5^{13} \pmod{77} = 26 \times = y^d \pmod{m} = 26^{37} \pmod{77} = 5$

Note: 384-bit primes or larger are deemed sufficient to use RSA securely. The prime number $e = 2^{16} + 1$ is often used in modern RSA implementations *[2,3]*.

Chosen-Ciphertext Attack

Z_n is a set of all positive integers from 0 to $(n-1)$. Z_{n^*} is a set all integers such that $\gcd(n,a)=1$, where $a \in Z_{n^*}$

$$Z_n^* \subset Z_n$$

$\Phi(n)$ calculates the number of elements in Z_{n^*} that are smaller than n and coprime to n.

$$\Phi(21)=\Phi(3)\times\Phi(7)=2\times6=12$$

Therefore, the number of integers in $\in Z_{21^*}$ is 12.

$$Z_{21}^*=\{1,2,4,5,8,10,11,13,16,17,19,20\}$$

Each of which is coprime to 21.

$$Z_{14}^*=\{1,3,5,9,11,13\}$$

Each of which is coprime to 14.

$$\Phi(14)=\Phi(2)\times\Phi(7)=1\times6=6 \text{ number of integers in } Z_{14}^*$$

Example: Choose $p=3$ and $q=7$, then $m=3\times7=21$.

Encryption and decryption take place in the ring, $R=<Z_{21},+,x>$

$$\Phi(21)=\Phi(2)\ \Phi\ (6)=12$$

Key-Generation Group, $G=<Z_{12}{}^*, x>$

$$\Phi(12)=\Phi(4)\Phi(3)=2\times2=4 \text{ number in}$$

$$Z_{12}^*=\{1,5,7,11\}$$

Alice encrypts the message P using the public key e of Bob and sends the encrypted message C to Bob.

$$C=P^e \bmod m$$

Eve, the middleman, intercepts the message and manipulates the message before forwarding to Bob.

1. Eve chooses a random integer $X \in Z_m^*$ (since m is public).
2. Eve calculates $Y=C\times X^e$ (mod m).
3. Bob receives Y from Eve, and he decrypts Y using his private key d.
4. $Z=Y^d$ (mod m).
5. Eve can easily discover the plaintext P as follows:

$$Z=Y^d \text{ (mod m)}=[C\times X^e]^d \text{ (mod m)}$$
$$=[C^d\times X^{ed}] \text{ (mod m)}=[C^d\times X] \text{ (mod m)}$$

Hence $Z=[P\times X]$ (mod m).

Using the Extended Euclidean algorithm, Eve can then compute the multiplicative inverse of X, and thus obtain P:

$$P=Z\times X^{-1} \text{ (mod m) [2,3]}$$

reduces to computing a, given (g, p, g^a mod p) for a randomly chosen $a<(p-1)$.

If we want to find the k^{th} power of one of the numbers in this group, we can do so by finding its k^{th} power as an integer and then finding the remainder after division by p. This process is called *discrete exponentiation*. For example, consider Z_{23^*}. To compute 3^4 in this group, we first compute $3^4=81$, then we divide 81 by 23, obtaining a remainder of 12. Thus $3^4=12$ in the group Z_{23^*}

A *discrete logarithm* is just the inverse operation. For example, take the equation $3^k\equiv12$ (mod 23) for k. As shown above $k=4$ is a solution, but it is not the only solution. Since $3^{22}\equiv1$ (mod 23), it also follows that if n is an integer, then $3^{4+22n}\equiv12\times1^n\equiv12$ (mod 23). Hence the equation has infinitely many solutions of the form $4+22n$. Moreover, since 22 is the smallest positive integer m satisfying $3^m\equiv1$ (mod 23), that is, 22 is the order of 3 in Z_{23^*} these are all solutions. Equivalently, the solution can be expressed as $k\equiv4$ (mod 22) [2,3].

The e^{th} Roots Problem

Given:

A composite number n, product of two prime numbers p and q

An integer $e\geq3$

$\gcd(e, \Phi(n))=1$

An integer $c\in Z_{12}{}^*$

Find an integer m such that $m^e\equiv c$ mod n[2,3].

10. DIFFIE-HELLMAN ALGORITHM

The purpose of this protocol is to allow two parties to set up a shared secret key over an insecure communication channel so that they may exchange messages. Alice and Bob agree on a finite cyclic group G and a generating element g in G. We will write the group G multiplicatively [2,3].

1. Alice picks a prime number p, with the base g, exponent a to generate a public key A
2. $A=g^a$ mod p
3. (g, p, A) are made public, and a is kept private.
4. Bob picks a prime number p, base b, and an exponent b to generate a public key B.
5. $B=g^b$ mod p
6. (g, p, B) are made public, and b is kept private,
7. Bob using A generates the shared secret key S.
8. $S=A^b$ mod p
9. Alice using B generates the shared secret key S.
10. $S=B^a$ mod p

Thus the shared secret key S is established between Bob and Alice.

Example:

Alice: p = 53, g = 18, a = 10
$A = 18^{10} \bmod 53 = 24$
Bob: p = 53, g = 18, b = 11
$B = 18^{11} \bmod 53 = 48$
$S = 24^{11} \bmod 53 = 48^{10} \bmod 53 = 15$

Diffie-Hellman Problem

The middleman Eve would know (*g*, *p*, *A*, *B*) since these are public. So for Eve to discover the secret key *S*, she would have to tackle the following two congruences:

$$g^a \equiv A \bmod p \quad \text{and} \quad g^b \equiv B \bmod p$$

If Eve had some way of solving the discrete logarithm problem (DLP) in a time-efficient manner, she could discover the shared secret key S; no probabilistic polynomial-time algorithm exists that solves this problem. The set of values:

$$(g^a \bmod p,\ g^b \bmod p,\ g^a b \bmod p)$$

is called the *Diffie-Hellman problem*.

If the DLP problem can be efficiently solved, then so can the Diffie-Hellman problem.

11. ELLIPTIC CURVE CRYPTOSYSTEMS

For simplicity, we shall restrict our attention to elliptic curves over *Zp*, where *p* is a prime greater than 3. We mention, however, that elliptic curves can more generally be defined over any finite field [4]. An *elliptic curve E* over Z_p is defined by an equation of the form

$$y^2 = x^3 + ax + b \qquad ((37.1))$$

where $a, b \in Z_p$, and $4a^3 + 27b^2 \neq 0 \pmod p$, together with a special point *O* called the *point at infinity*. The set *E* (Z_p) consists of all points (*x, y*), $x \in Z_p$, $y \in Z_p$, which satisfy the defining equation (1), together with *O*.

An Example

Let $p = 23$ and consider the elliptic curve $E\!: y^2 = x^3 + x + 1$, defined over Z_{23}. (In the notation of Equation 24.1, we have $a = 1$ and $b = 1$.) Note that $4a^3 + 27b^2 = 4 + 4 = 8 \neq 0$, so *E* is indeed an elliptic curve. The points in $E(Z_{23})$ are *O* and the following are shown in Table 37.18.

Addition Formula

There is a rule for adding two points on an elliptic curve *E(Zp)* to give a third elliptic curve point. Together with this addition operation, the set of points *E(Zp)* forms a group with *O* serving as its identity. It is this group that is used in the construction of elliptic curve cryptosystems.

TABLE 37.18 Elliptic Curve Cryptosystems.

(0, 1)	(6, 4)	(12, 19)
(0, 22)	(6, 19)	(13, 7)
(1, 7)	(7, 11)	(13, 16)
(1, 16)	(7, 12)	(17, 3)
(3, 10)	(9, 7)	(17, 20)
(3, 13)	(9, 1 6)	(18, 3)
(4, 0)	(11, 3)	(18, 20)
(5, 4)	(11, 20)	(19, 5)
(5, 19)	(12, 4)	(19, 18)

The addition rule, which can be explained geometrically, is presented here as a sequence of algebraic formula [4].

1. $P + O = O + P = P$ for all $P \in E(Z_p)$
2. If $P = (x, y) \in E(Zp)$ then $(x, y) + (x, -y) = O$ (The point $(x, -y)$ is denoted by $-P$, and is called the *negative* of *P*; observe that $-P$ is indeed a point on the curve.)
3. Let $P = (x1,y1) \in E(Zp)$ and $Q = (x2,y2) \in E(Zp)$, where $P \neq -Q$. Then $P + Q = (x3,y3)$,

where:

$$x_3 = (\lambda^2 - x_1 - x_2) \bmod p$$
$$y_3 = (\lambda(x_1 - x_3) - y_1) \bmod p$$
$$\lambda = \frac{y_2 - y_1}{x_2 - x_1} \bmod p \text{ if } P \neq Q \text{ or}$$
$$\lambda = \frac{3x_1^2 + \alpha}{2y_1} \bmod p \text{ if } P = Q$$

We will digress to modular division: 4/3 mod 11. We are looking for a number, say *t*, such that 3 * *t* mod 11 = 4. We need to multiply the left and right sides by 3^{-1}

$$3^{-1} * 3 * t \bmod 11 = 3^{-1} * 4$$
$$t \bmod 11 = 3^{-1} * 4$$

Next we use the Extended Euclidean algorithm and get (inverse) 3^{-1} is 4 (3 * 4 = 12 mod 11 = 1).

$$4 * 4 \bmod 11 = 5$$

Hence,

$$4/3 \bmod 11 = 5$$

Example of Elliptic Curve Addition

Consider the elliptic curve defined in the previous example. (Also see sidebar, "EC Diffie-Hellman Algorithm.") [4].

EC Diffie-Hellman Algorithm

1. Alice has her elliptic curve, and she chooses a secret random number d and computes a number on the curve $Q_A = d_A * P$[4].
   Alice's public key: (p, a, b, Q_A)
   Alice's private key: d_A
2. Bob has his elliptic curve, and he chooses a secret random number d and computes a number on the curve $Q_B = d_B * P$:
   Bob's public key: (p, a, b, Q_B)
   Bob's private key: d_B
3. Alice computes the shared secret key as
$$S = d_A * Q_B$$
4. Similarly, Bob computes the shared secret key as
$$S = d_B * Q_A$$
5. The shared secret key computed by Alice and Bob are the same for:
$$S = d_B * Q_A = d_B * d_A * P$$

1. Let $P = (3, 10)$ and $Q = (9, 7)$. Then $P + Q = (x3, y3)$ is computed as follows:
$$\lambda = \frac{7-10}{9-3} = \frac{-3}{6} = \frac{-1}{2} = 11 \in Z_{23}$$
$x_3 = 11^2 - 3 - 9 = 6 - 3 - 9 = -6 \equiv 17 \pmod{23}$, and $y_3 = 11(3 - (-6)) \quad -10 = 11(9) \quad -10 = 89 \equiv 20 \pmod{23}$.

   Hence $P + Q = (17, 20)$.
2. Let $P = (3,10)$. Then $2P = P + P = (x_3, y_3)$ is computed as follows:
$$\lambda = \frac{3(3^2)+1}{20} = \frac{5}{20} = \frac{1}{4} = 6 \in Z_{23}$$
$x_3 = 6^2 - 6 = 30 \equiv 7 \pmod{23}$, and $y_3 = 6\,(3-7) - 10 = -24 - 10 = -11 \in 12 \pmod{23}$.
   Hence $2P = (7, 12)$.
   Consider the following elliptic curve with Z_p^*
$$y^2 \bmod p = (x^3 + ax + b) \bmod p$$

Set $p = 11$ and $a = 1$ and $b = 2$. Take a point P (4, 2) and multiply it by 3; the resulting point will be on the curve with (4, 9).

EC Security

Suppose Eve the middleman captures (p, a, b, Q_A, Q_B). Can Eve figure out the shared secret key without knowing either (d_B, d_A)? Eve could use
$$Q_A = P * d_A$$
to compute the unknown d_A, which is known as the Elliptic Curve Discrete Logarithm problem [4].

12. MESSAGE INTEGRITY AND AUTHENTICATION

We live in the Internet age, and a fair number of commercial transactions take place on the Internet. It has often been reported that transactions on the Internet between two parties have been hijacked by a third party, hence data integrity and authentication are critical if ecommerce is to survive and grow.

This section deals with message integrity and authentication. So far we have discussed and shown how to keep a message confidential. But on many occasions we need to make sure that the content of a message has not been changed by a third party, and we need some way of ascertaining whether the message has been tampered with. Since the message is transmitted electronically as a string of ones and zeros, we need a mechanism to make sure that the count of the number of ones and zeros does not become altered, and furthermore, that zeros and ones are not changed in their position within the string.

We create a pair and label it as message and its corresponding message digest. A given block of messages is run through an algorithm hash function, which has its input the message and the output is the compressed message, the message digest, which is a fixed-size block but smaller in length. The receiver, say, Bob, can verify the integrity of the message by running the message through the hash function (the same hash function as used by Alice) and comparing the message digest with the message digest that was sent along with the message by, say, Alice. If the two message digests agree on their block size, the integrity of the message was maintained in the transmission.

Cryptographic Hash Functions

A cryptographic hash function must satisfy three criteria:

- Preimage resistance
- Second preimage resistance (weak collision resistance)
- Strong collision resistance

Preimage Resistance

Given a message m and the hash function hash, if the hash value h = hash(m) is given, it should be hard to find any m such that h = hash(m).

Second Preimage Resistance (Weak Collision Resistance)

Given input m_1, it should be hard to find another message m_2 such that hashing) = hash(m_2) and that $m_1 \neq m_2$

Strong Collision Resistance

It ought to be hard to find two messages $m_1 \neq m_2$ such that hash(m_1) = hash(m_2). A hash function takes a fixed size input *n*-bit string and produces a fixed size output *m*-bit string such that *m* less than *n* in length. The original hash function was defined by Merkle-Damgard, which is an iterated hash function. This hash function first breaks up the original message into fixed-size blocks of size *n*. Next an initial vector H_0 (digest) is set up and combined with the message block M_1 to produce message digest H_1, which is then combined with M_2 to produce message digest H_1, and so on until the last message block produces the final message digest.

$$H_i = f(H_{i-1}, M_i) \quad i \geq 1$$

Message digest MD2, MD4, and MD5 were designed by Ron Rivest. MD5 as input block size of 512 bits and produces a message digest of 128 bits [1].

Secure Hash Algorithm (SHA) was developed by the National Institute of Standards and Technology (NIST). SHA-1, SHA-224, SHA-256, SHA-384, and SHA-512 are examples of the secure hash algorithm. SHA-512 produces a message digest of 512 bits.

Message Authentication

Alice sends a message to Bob. How can Bob be sure that the message originated from Alice and not someone else pretending to be Alice? If you are engaged in a transaction on the Internet using a Web client, you need to make sure that you are not engaged with a dummy Web site or else you could submit your sensitive information to an unauthorized party. Alice in this case needs to demonstrate that she is communicating and not an imposter.

Alice creates a message digest using the message (M), then using the shared secret key (known to Bob only) she combines the key with a message digest and creates a message authentication code (MAC). She then sends the MAC and the message (M) to Bob over an insecure channel. Bob uses the message (M) to create a hash value and then recreates a MAC using the secret shared key and the hash value. Next he compares the received MAC from Alice with his MAC. If the two match, Bob is assured that Alice was indeed the originator of the message [1].

Digital Signature

Message authentication is implemented using the sender's private key and verified by the receiver using the sender's public key. Hence if Alice uses her private key, Bob can verify that the message was sent by Alice, since Bob would have to use Alice's public key to verify. Alice's public key cannot verify the signature signed by Eve's private key [1].

Message Integrity Uses a Hash Function in Signing the Message

Nonrepudiation is implemented using a third party that can be trusted by parties that want to exchange messages with one another. For example, Alice creates a signature from her message and sends the message, her identity, Bob's identity, and the signature to the third party, who then verifies the message using Alice's public key that the message came from Alice. Next the third party saves a copy of the message with the sender's and the recipient's identity and the time stamp of the message.

The third party then creates another signature using its private key from the message that Alice left behind. The third party then sends the message, the new signature, and Alice's and Bob's identity to Bob, who then uses the third party's public key to ascertain that the message came from the third party [1].

RSA Digital Signature Scheme

Alice and Bob are the two parties that are going to exchange the messages. So, we begin with Alice, who will generate her public and private key using two distinct prime numbers—say, *p* and *q*. Next she calculates $n = p \times q$. Using $\Phi(n) = (p-1)(q-1)$, picks *e* and computes *d* such that $e \times d = 1 \bmod (\Phi(n)$. Alice declares (e, n) public, keeping her private key *d* secret.

Signing: Alice takes the message and computes the signature as:

$$S = M^d (\text{mod } n)$$

She then sends the message *M* and the signature *S* to Bob.

Bob receives the message M and the signature S, and then, using Alice's public key *e* and the signature S, recreates the message $M' = S^e$ (mod *n*). Next Bob compares M′ with M, and if the two values are congruent, Bob accepts the message [1].

RSA Digital Signature and the Message Digest

Alice and Bob agree on a hash function. Alice applies the hash function to the message M and generates the message digest, D = hash(M). She then signs the message digest using her private key,

$$S = D^d (\text{mod } n)$$

Alice sends the signature S and the message M to Bob. He then uses Alice's public key, and the signature S recreates the message digest D' = S^e (mod n) as well as computes the message digest D = hash(M) from the received message M. Bob then compares D with D', and if they are congruent modulo n, he accepts the message [1].

Next, let's take a very very brief look at the Triple Data Encryption Algorithm (TDEA), including its primary component cryptographic engine, the Data Encryption Algorithm (DEA). When implemented, TDEA may be used by organizations to protect sensitive unclassified data. Protection of data during transmission or while in storage may be necessary to maintain the confidentiality and integrity of the information represented by the data.

13. TRIPLE DATA ENCRYPTION ALGORITHM (TDEA) BLOCK CIPHER

TDEA is made available for use by organizations and Federal agencies within the context of a total security program consisting of physical security procedures, good information management practices, and computer system/network access controls. The TDEA block cipher includes a Data Encryption Algorithm (DEA) cryptographic engine that is implemented as a component of TDEA. TDEA functions incorporating the DEA cryptographic engine are designed in such a way that they may be used in a computer system, storage facility, or network to provide cryptographic protection to binary coded data. The method of implementation will depend on the application and environment. TDEA implementations are subject to being tested and validated as accurately performing the transformations specified in the TDEA algorithm.

Applications

Cryptography is utilized in various applications and environments. The specific utilization of encryption and the implementation of TDEA is based on many factors particular to the computer system and its associated components. In general, cryptography is used to protect data while it is being communicated between two points or while it is stored in a medium vulnerable to physical theft or technical intrusion (hacker attacks). In the first case, the key must be available by the sender and receiver simultaneously during communication. In the second case, the key must be maintained and accessible for the duration of the storage period. The following checklist (see checklist: "An Agenda For Action Of Conformance Requirements For The Installation, Configuration And Use Of TDEA") lays out an agenda for action for conformance to many of the requirements that are the responsibility of entities installing, configuring or using

An Agenda for Action of Conformance Requirements for the Installation, Configuration and Use of TDEA

These requirements include the following (Check All Tasks Completed):

_____**1.** TDEA functions incorporating the DEA cryptographic engine shall be designed in such a way that they may be used in a computer system, storage facility, or network to provide cryptographic protection to binary coded data.

_____**2.** Each 64-bit key shall contain 56 bits that are randomly generated and used directly by the algorithm as key bits.

_____**3.** A key bundle shall not consist of three identical keys.

_____**4.** The TDEA block cipher shall be used to provide cryptographic security only when used in an approved mode of operation.

_____**5.** The following specifications for keys shall be met in implementing the TDEA modes of operation. The bundle and the individual keys shall:

- _____**a.** Be kept secret.
- _____**b.** Be generated using an approved method12 that is based on the output of an approved random bit generator.
- _____**c.** Be independent of other key bundles.
- _____**d.** Have integrity whereby each key in the bundle has not been altered in an unauthorized manner since the time it was generated, transmitted, or stored by an authorized source.
- _____**e.** Be used in the appropriate order as specified by the particular mode.
- _____**f.** Be considered a fixed quantity in which an individual key cannot be manipulated while leaving the other two keys unchanged; and cannot be unbundled except for its designated purpose.

_____**6.** One key bundle shall not be used to process more than 232 64-bit data blocks when the keys conform to Keying Option 1.

_____**7.** When Keying Option 2 is used, the keys shall not be used to process more than 220 blocks.

applications or protocols that incorporate the recommended use of TDEA.

14. SUMMARY

In this chapter we have attempted to cover cryptography from its very simple structure such as substitution ciphers to the complex AES and elliptic curve crypto-systems. There is a subject known as *cryptoanalysis* that attempts to crack the encryption to expose the key, partially or fully. We briefly discussed this in the section on the discrete logarithm problem. Over the past 10 years, we have seen the application of quantum theory to encryption in what is termed *quantum cryptology*, which is used to transmit the secret key securely over a public channel. The reader will observe that we did not cover the Public Key Infrastructure (PKI) due to lack of space in the chapter.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Data security is limited to wired networks but is equally critical for wireless communications such as in Wi-Fi and cellular.
2. True or False? Data communication normally takes place over a secured channel, as is the case when the Internet provides the pathways for the flow of data.
3. True or False? The encryption of the message can be defined as *mapping* the message from the domain to its range such that the inverse mapping should recover the original message.
4. True or False? Information security is the goal of the secured data encryption; hence if the encrypted data is truly randomly distributed in the message space (range), to the hacker the encrypted message is equally unlikely to be in any one of the states (encrypted).
5. True or False? Computational complexity deals with problems that could be solved in polynomial time, for a given input.

Multiple Choice

1. The conceptual foundation of _________ was laid out around 3,000 years ago in India and China.
   A. Cryptography
   B. Botnets
   C. Data retention
   D. Evolution
   E. Security
2. In cryptography we use _________ to express that the residue is the same for a set of integers divided by a positive integer.
   A. Congruence
   B. Traceback
   C. Data retention
   D. Process
   E. Security
3. What is a set of integers congruent mod m, where m is a positive integer?
   A. Evolution
   B. Residue class
   C. Peer-to-peer (P2P)
   D. Process
   E. Security
4. _________________also known as *additive ciphers*, are an example of a monoalphabetic character cipher in which each character is mapped to another character, and a repeated character maps to the same character irrespective of its position in the string:
   A. Security
   B. Data retention
   C. Shift ciphers
   D. Cyber crimes
   E. Evolution
5. A transposition cipher changes the location of the character by a given set of rules known as:
   A. Physical world
   B. Data retention
   C. Standardization
   D. Permutation
   E. All of the above

EXERCISE

Problem

How is the DEA cryptographic engine used by TDEA to cryptographically protect (encrypt) blocks of data consisting of 64 bits under the control of a 64-bit key?

Hands-On Projects

Project

Please expand on a discussion of how each TDEA forward and inverse cipher operation is a compound operation of the DEA forward and inverse transformations.

Case Projects

Problem

For all TDEA modes of operation, three cryptographic keys (***Key*1**, ***Key*2**, ***Key*3**) define a TDEA key bundle. The bundle and the individual keys should do what?

Optional Team Case Project

Problem

There are a few keys that are considered weak for the DEA cryptographic engine. The use of weak keys can reduce the effective security afforded by TDEA and should be avoided. Give an example of Keys that are considered to be weak (in hexadecimal format).

Satellite Encryption

Daniel S. Soper

Information Systems and Decision Sciences Department, Mihaylo College of Business and Economics, California State University, Fullerton, dsoper@fullerton.edu

1. INTRODUCTION

For virtually all of human history, the communication of information was relegated to the surface of the Earth. Whether written or spoken, transmitted by land, by sea, or by air, all messages had one thing in common – they were, like those who created them, inescapably bound to the terrestrial surface. In February 1945, however, the landscape of human communication was forever altered when an article by the highly influential science fiction writer Arthur C. Clarke proposed the extraordinary possibility that artificial satellites placed into orbit above the Earth could be used to facilitate mass communication on a global scale. A year later, a Project RAND report concluded that "A satellite vehicle with appropriate instrumentation [could] be expected to be one of the most potent scientific tools of the 20th century", and that "The achievement of a satellite craft would produce repercussions comparable to the explosion of the atomic bomb." It was only 12 short years after Clarke's historic prediction that mankind's first artificial satellite, *Sputnik 1*, was transmitting information from orbit back to Earth. In the decades that followed, satellite technology evolved rapidly from its humble beginnings to become an essential tool for such diverse activities as astronomy, commerce, communications, scientific research, defense, navigation, and the monitoring of global climate conditions. In the 21st century, satellites are helping to fuel globalization, and societies everywhere are relying heavily on the power of satellite technology to enable the modern lifestyle. It is for these reasons that satellite communications must be protected. Before examining satellite encryption in particular, however, a brief review of satellite communication in general may be useful.

For communications purposes, modern satellites can be classified into two categories: those that communicate exclusively with the surface of the Earth (which will be referred to here as "Type 1" satellites), and those that communicate not only with the surface of the Earth, but also with other satellites or spacecraft (which will be referred to here as "Type 2" satellites). The distinction between these two types of satellite communication is depicted in Figure 38.1 below.

As shown in Figure 38.1, there are several different varieties of communications links that a particular

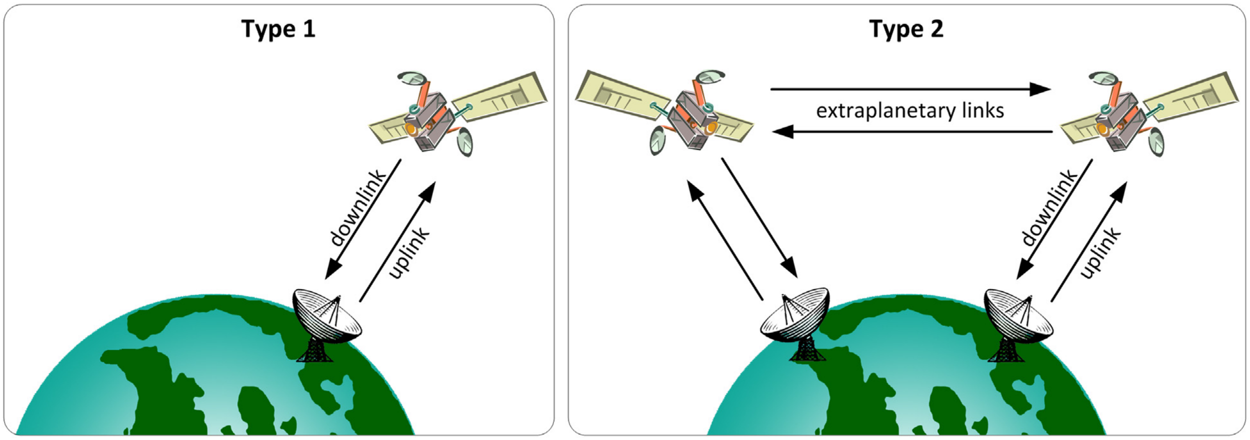

FIGURE 38.1 Comparison of Type 1 and Type 2 satellite communication capabilities.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00038-6

satellite may support. Classifying satellites as Type 1 or Type 2 provides us with a useful framework for understanding and discussing basic satellite communications capabilities, and allows us to gain insight into the sort of communications links that may need to be protected. In the case of Type 1 satellites, the spacecraft may support *uplink* capabilities, *downlink* capabilities, or both. An uplink channel is a communications channel through which information is transmitted from the surface of the Earth to an orbiting satellite or other spacecraft. By contrast, a downlink channel is a communications channel through which information is transmitted from an orbiting satellite or other spacecraft to the terrestrial surface. While Type 2 satellites may possess the uplink and downlink capabilities of a Type 1 satellite, they are also capable of establishing links with spacecraft or other Type 2 satellites for purposes of extraplanetary communication. Type 2 satellites that can act as an intermediary between other spacecraft and the terrestrial surface can be classified as relay satellites. Note that whether a particular link is used for sending or receiving information depends upon the perspective of the viewer. From the ground, for example, an uplink channel is used to send information, but from the perspective of the satellite, the uplink channel is used to receive information.

2. THE NEED FOR SATELLITE ENCRYPTION

Depending on the type of satellite communications link that needs to be established, substantially different technologies, frequencies, and data encryption techniques may be required in order to secure a satellite-based communications channel. The reasons for this lie as much in the realm of human behavior as they do in the realm of physics. Broadly speaking, it is not unreasonable to conclude that satellite encryption would be entirely unnecessary if every human being were perfectly trustworthy. That is to say, the desire to protect our messages from the possibility of extraterrestrial interception and decipherment notwithstanding, there would be no need to encrypt satellite communications if only those individuals entitled to send or receive a particular satellite transmission actually attempted to do so. In reality, however, human beings, organizations, and governments commonly possess competing or contradictory agendas, thus implying the need to protect the confidentiality, integrity, and availability of information transmitted via satellite.

Keeping such human behavioral concerns in mind, we can also understand the need for satellite encryption from a physical perspective. Consider, for example, a Type 1 communications satellite that has been placed into orbit above the equator of the Earth. Transmissions from the satellite to the terrestrial surface (the downlink channel) would commonly be made by way of a parabolic antenna. Although such an antenna facilitates focusing the signal, the signal nevertheless disperses in a conical fashion as it departs the spacecraft and approaches the surface of the planet. The result is that the signal may be made available over a wider geographic area than would be optimally desirable for security purposes. As with terrestrial radio, in the absence of encryption, anyone within range of the signal who possesses the requisite equipment could receive the message. In this particular example, the geographic area over which the signal would be dispersed would depend both on the focal precision of the parabolic antenna, and the altitude of the satellite above the Earth. These concepts are illustrated in Figure 38.2 below.

Because the sender of a satellite message may have little or no control over to whom the transmission is theoretically available, protecting the message requires that its contents be encrypted. For similar reasons, extraplanetary transmissions sent between Type 2 satellites must also be protected. After all, with thousands of satellites orbiting

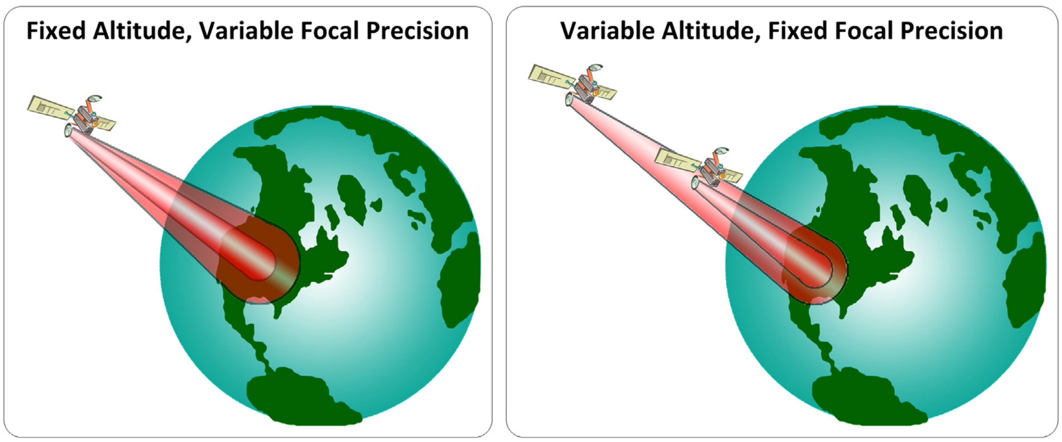

FIGURE 38.2 Effect of altitude and focal precision on satellite signal dispersion.

the planet, the chances of an inter-satellite communication being intercepted are quite good!

Aside from these considerations, the sensitivity of the information being transmitted must also be taken into account. Different entities possess different motivations for wanting to ensure the security of messages transmitted via satellite. An individual, for example, may want her private telephone calls or bank transaction details to be protected. An organization may likewise want to prevent its proprietary data from falling into the hands of its competition, while a government may want to protect its military communications and national security secrets from being intercepted or compromised by an enemy. As is the case with terrestrial communications, the sensitivity of the data being transmitted via satellite must dictate the extent to which those data are protected. If the emerging global Information Society is to fully capitalize on the benefits of satellite-based communication, its citizens, organizations, and governments must be assured that their sensitive data are not being exposed to unacceptable risk. In light of these considerations, satellite encryption will almost certainly play a key role in the future advancement of mankind.

3. IMPLEMENTING SATELLITE ENCRYPTION

It was noted earlier in this chapter that information can be transmitted to or from satellites using three general types of communication links: surface-to-satellite links (uplinks), satellite-to-surface links (downlinks), and inter-satellite or inter-spacecraft links (extraplanetary links). Technological considerations notwithstanding, the specific encryption mechanism used to secure a transmission depends not only on which of these three types of links is being utilized, but also on the nature and purpose of the message being transmitted. For purposes of simplicity, the value of transmitted information can be classified along two dimensions: high-value, and low-value. The decision as to what constitutes high-value and low value information largely depends on the perspective of the beholder — after all, one man's trash is another man's treasure. Nevertheless, establishing this broad distinction allows satellite encryption to be considered in the context of the conceptual model shown in Figure 38.3 below.

Type of Satellite Communications Link

Data Value	Uplink	Downlink	Extraplanetary Link
High-Value	Category 01	Category 03	Category 05
Low-Value	Category 02	Category 04	Category 06

FIGURE 38.3 Satellite communications categories as a function of data value and type of link.

As shown in Figure 38.3, any satellite-based communication can be classified into one of six possible categories. Each of these categories will be addressed later in the chapter by considering the encryption of both high-value and low-value data in the context of the three types of satellite communication links. Before considering the specific facets of encryption pertaining to satellite uplink, extraplanetary, and downlink transmissions, however, an examination of several of the more general issues associated with satellite encryption may be useful.

General Satellite Encryption Issues

One of the problems common to all forms of satellite encryption relates to signal degradation. Satellite signals are typically sent over long distances using comparatively low-power transmissions, and must frequently contend with many forms of interference, including terrestrial weather, solar and cosmic radiation, and many other forms of electromagnetic noise. Such disturbances can cause errors or gaps to emerge in the signal that carries a satellite transmission from its source to its destination. Depending on the encryption algorithm chosen, this situation can be particularly problematic for encrypted satellite transmissions, since the entire encrypted message may be irretrievably lost if even a single bit of data is out of place. To resolve this problem, a checksum or cryptographic hash function may be applied to the encrypted message to allow errors to be identified and reconciled upon receipt. This approach comes at a cost however — appending checksums or error-correcting code to an encrypted message increases the length of the message, and by extension increases the time required for the message to be transmitted. The result, of course, is that a satellite's actual overall communications capacity is commonly lower than its theoretical capacity, due to the extra burden that is placed on its limited resources by this communications overhead.

Another common problem associated with two-way encrypted satellite communications relates to establishing the identity of the sender of a message. Most modern satellites, for example, are designed to receive and respond to signals that control their onboard functions. Such satellites need to be certain that the control signals they receive from the ground originate from an authorized source. In addition to control signals, senders of other types of satellite transmissions commonly need to be authenticated as well. An intelligence agency receiving a satellite transmission from one of its operatives, for example, needs to establish that the transmission is genuine. To establish the identity of the sender, the message needs to be encrypted in such a way that from the recipient's perspective, only a legitimate sender could have encoded the message. The sender, of course, also wants

to ensure that the message is protected while in transit, and thus desires that only an authorized recipient would be able to decode the message upon receipt. Both parties to the communication must therefore agree to use an encryption algorithm that serves to identify the authenticity of the sender while affording a sufficient level of protection to the message while it is in transit to its destination. Although keyless encryption algorithms may satisfy these two criteria, such algorithms are usually avoided in satellite communications, since the satellite may become useless if the keyless encryption algorithm were to be compromised, and satellites are expensive to replace. This problem also extends to the terrestrial equipment used to encrypt satellite signals prior to transmission and decrypt those signals after receipt. Keyed encryption algorithms are therefore typically used to protect information transmitted via satellite. Even keyed methods of encryption can be problematic when it comes to satellite communications, however.

To gain insight into the problems associated with keyed encryption, one might first consider the case of a symmetrically keyed encryption algorithm, wherein the same key is used to both encode and decode a message. If party *A* wants to communicate with party *B* via satellite using this method, then both *A* and *B* must agree on a secret key in advance of the communication. As long as the key remains secret, it also serves to authenticate both parties. If party *A* also wants to communicate with party *C*, however, then *A* and *C* must agree on their own unique secret key, otherwise party *B* could masquerade as *A* or *C*, and vice-versa. A keyed encryption approach to two-way satellite communication thus requires that each party establish a unique secret key with every other party with whom they would like to communicate. To further compound this problem, each party must obtain all of its secret keys in advance, because possession of an appropriate key is a necessary prerequisite to establishing a secure communications channel with another party.

To resolve these issues, an asymmetrically keyed encryption algorithm may be adopted, wherein the key used to encrypt a message is different from the key used to decrypt the message. Such an approach requires each party to maintain only two keys, one of which is kept private, and the other of which is made publicly-available. If party *A* wants to send party *B* a secure transmission, *A* first asks *B* for her public key, which can be transmitted over an unsecured connection. Party *A* then encodes a secret message using *B's* public key. The message is secure because only *B's* private key can decode the message. To authenticate herself to *B*, party *A* needs only to re-encode the entire message using her own private key before transmitting the message to *B*. Upon receiving the message, *B* can establish whether it was sent by *A*, because only *A's* private key could have encoded a message that can be decoded with *A's* public key. This process is depicted in Figure 38.4 below.

Unfortunately, even this approach to secure two-way satellite communication is not entirely foolproof. To understand why, consider how a malicious party *M* might interject himself between *A* and *B* in order to intercept

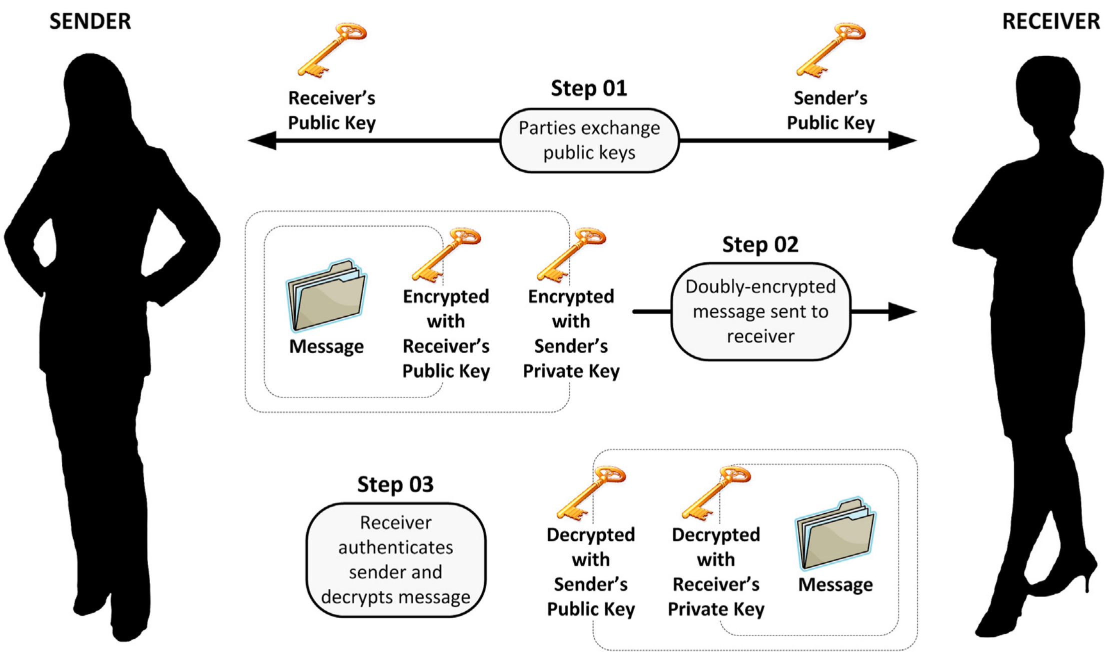

FIGURE 38.4 Ensuring sender identity and message security with asynchronously keyed encryption.

the secure communication. To initiate the secure transmission, *A* must request *B's* public key over an unsecure channel. If this request is intercepted by *M*, then *M* can supply *A* with his own (that is, *M's*) public key. *A* will then encrypt the message with *M's* public key, after which she will re-encrypt the result of the first encryption operation with her own private key. *A* will then transmit the encrypted message to *B*, which will once again be intercepted by *M*. Using *A's* public key in conjunction with his own private key, *M* will be able to decrypt and read the message. *A* will not know that the message has been intercepted, and *B* will not know that a message was even sent. Note that intercepting a secure communication is particularly easy for *M* if he owns or controls the satellite through which the message is being routed. In addition to the risk of interception, asynchronously keyed encryption algorithms are typically at least 10,000 times slower than synchronously keyed encryption algorithms – a situation that may place an enormously large burden on a satellite's limited computational resources. Until a means is developed of dynamically and securely distributing synchronous keys, satellite-based encryption will always require trade-offs among security, computational complexity, and ease of implementation.

Uplink Encryption

Protecting a transmission that is being sent to a satellite from at or near the surface of the Earth requires much more than just cryptographic techniques; to wit, encrypting the message itself is a necessary but insufficient condition for protecting the transmission. The reason for this is that the actual transmission of the encrypted message to the satellite is but the final step in a long chain of custody that begins when the message is created and ends when the message is successfully received by the satellite. Along the way, the message may pass through many people, systems, or networks, the control of which may or may not reside entirely in the hands of the sender. If one assumes that the confidentiality and integrity of the message have not been compromised as the message has passed through all of these intermediaries, then but two primary security concerns remain: the directional accuracy of the transmitting antenna, and the method used to encrypt the message. In the case of the former, the transmitting antenna must be sufficiently well-focused to allow the signal to be received by – and ideally *only* by – the target satellite. With thousands of satellites in orbit, a strong potential exists for a poorly focused transmission to be intercepted by another satellite, in which case the only remaining line of defense for a message is the strength of the encryption algorithm with which it was encoded. For this reason, a prudent sender should always assume that their message could be intercepted while in transit to and from the satellite, and should implement message encryption accordingly.

When deciding upon which encryption method to use, the sender must simultaneously consider the value of the data being transmitted, the purpose of the transmission, and the technological and computational limitations of the target satellite. A satellite's computational and technological capabilities are a function of its design specifications, its current workload, and any degradation that has occurred since the satellite was placed into orbit. These properties of the satellite can therefore be considered constraints – any encrypted uplink communications must work within the boundaries of these limitations. That having been said, the purpose of the transmission also features prominently in the choice of which encryption method to use. Here we must distinguish between two types of transmissions: commands, which instruct the satellite to perform one or more specific tasks, and transmissions-in-transit, which are intended to be retransmitted to the surface or to another satellite or spacecraft. Not only are command instructions of high value, but they are also not typically burdened with the same low-latency requirements of transmissions-in-transit. Command instructions should therefore always be highly encrypted, because control of the satellite could be lost if they were to be intercepted and compromised. What remains, then, are transmissions-in-transit, which may be of either high value, or of low value. One of the basic tenants of cryptography states that the value of the data should dictate the extent to which the data are protected. As such, minimal encryption may be acceptable for low-value transmissions-in-transit. For such transmissions, adding an unnecessarily complex layer of encryption may increase the computational burden on the satellite, which in turn may delay message delivery and limit the satellite's ability to perform other tasks simultaneously. High-value transmissions-in-transit should be protected with a robust encryption scheme that reflects the value of the data being transmitted. The extent to which a highly encrypted transmission-in-transit will negatively impact a satellite's available resources depends upon whether or not the message needs to be processed before being retransmitted. If the message is simply being relayed through the satellite without any additional processing, then the burden on the satellite's resources may be comparatively small. If, however, a highly encrypted message needs to be processed by the satellite prior to retransmission (if the message needs to be decrypted, processed, and then re-encrypted), the burden on the satellite's resources may be substantial. Processing high-value, highly encrypted transmissions-in-transit may therefore vastly reduce a satellite's throughput capabilities when considered in conjunction with its technological and computational limitations.

Extraplanetary Link Encryption

Before a signal is sent to the terrestrial surface, it may need to be transmitted across an extraplanetary link. Telemetry from a remote spacecraft orbiting Mars, for example, may need to be relayed to scientists by way of an Earth-orbiting satellite. Alternatively, a television signal originating in China may need to be relayed around the Earth by several intermediary satellites in order to reach its final destination in the United States. In such circumstances, several unique encryption-related issues may arise, each of which is associated with the routing of an extraplanetary transmission through one or more satellite nodes. Perhaps the most obvious of these issues is the scenario that arises when the signal transmitted from the source satellite or spacecraft is not compatible with the receiving capabilities of the target. For example, the very low power signals transmitted from a remote exploratory spacecraft may not be detectable by a particular listening station on the planet's surface, or the data rate or signal modulation with which an extraplanetary transmission is sent may not be supported by the final recipient. In this scenario, the intermediary satellite through which the signal is being routed must act as an interpreter or translator of sorts, a situation which is illustrated in Figure 38.5 below.

From an encryption perspective, the situation illustrated above implies that the intermediary satellite may need to decrypt the extraplanetary message, and re-encrypt it using a different encryption scheme prior to retransmission. A similar issue may arise for legal or political reasons. Consider, for example, a message that is being transmitted from one country to another by way of several intermediary satellites. The first country may have no standing policies regarding the encryption of messages sent via satellite, while the second country may have policies that strictly regulate the encryption standards of messages received via satellite. In this case, one or more of the orbiting satellites may need to alter the encryption of a message in transit in order to satisfy the legal and regulatory guidelines of both countries.

Downlink Encryption

Several different issues impact the way in which information is protected as it is transmitted from orbiting satellites to the surface of the Earth. As with uplink encryption, the technological and computational capabilities of the spacecraft may constrain the extent to which a particular message can be protected. If, for example, an older communications satellite does not possess the requisite hardware or software capabilities to support a newly developed downlink encryption scheme, then that scheme simply cannot be used with the satellite. Similarly, if the utilization of a particular encryption scheme would reduce the efficiency or message-handling capacity of a satellite to a level that is deemed unacceptable, then the satellite's operators may choose to prioritize capacity over downlink security. The precision with which a satellite is able to focus a downlink transmission may also impact the choice of encryption scheme — as noted earlier in this chapter, a widely dispersed downlink signal can be more readily intercepted than can a signal transmitted with a narrow focus. While each of these computational and technological limitations must be considered when selecting a downlink encryption scheme, they are by no means the only factors requiring consideration.

Unlike uplink signals, which can only originate from the surface of the planet, messages to be transmitted over a downlink channel can come from one of three different sources: the terrestrial surface, from another spacecraft, or from the satellite itself. The source of the message to be broadcast to the planet's surface plays a critical role in determining the method of protection for that message. Consider, for example, a message that originates from the surface or from another spacecraft. In

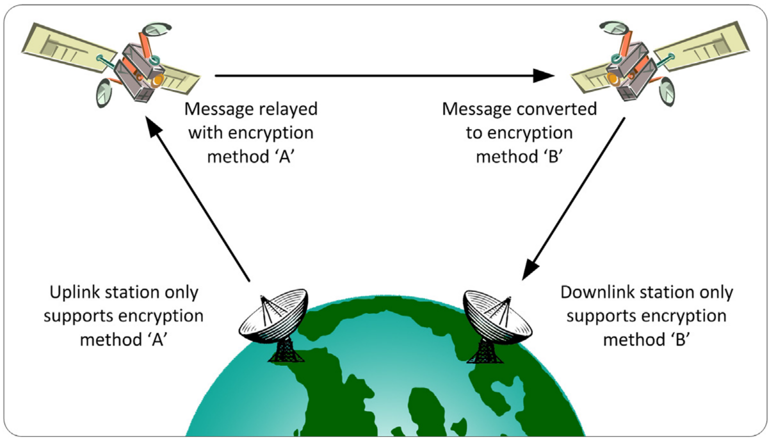

FIGURE 38.5 In-transit translation of encrypted messages in satellite communication.

this case, one of two possible scenarios may exist. First, the satellite transmitting the message to Earth may be serving only as a simple signal repeater or amplifying transmitter; that is to say, the message is already encrypted upon receipt, and the satellite is simply relaying the previously encrypted message to the surface. In this case, the satellite transmitting the downlink signal has very little to do with the encryption of the message, and only the integrity of the message and the retransmission capabilities of the satellite at the time the message is received need be considered. In the second scenario, a satellite may need to filter a message or alter its encryption method prior to downlink transmission. For example, a satellite may receive signals that have been optimized for extraplanetary communication from a robotic exploration spacecraft in the far reaches of the solar system. Prior to retransmission, the satellite may need to decrypt the data, process it, and then re-encrypt the data using a different encryption scheme more suited to a downlink transmission. In this case, the technological capabilities of the satellite, the timeliness with which the data need to be delivered, and the value of the data themselves dictate the means through which those data are protected prior to downlink transmission.

Finally, one might consider the scenario in which the data being transmitted to the terrestrial surface originate from the satellite itself, rather than from the surface or from another spacecraft. Such data can be classified as either telemetry relating to the status of the satellite, or as information that the satellite has acquired or produced while performing an assigned task. In the case of the former, telemetry relating to the status of the satellite should always be highly protected, as it may reveal details about the satellite's capabilities, inner workings, or control systems if it were to be intercepted and compromised. In the case of the latter, however, the value of the data that the satellite has acquired or produced should dictate the extent to which those data are protected. Critical military intelligence, for example, should be subjected to a much higher standard of encryption than data that are comparatively less valuable. In the end, a satellite operator must weigh many factors when deciding upon the extent to which a particular downlink transmission should be protected. It is tempting to conclude that the maximum level of encryption should be applied to every downlink transmission. Doing so, however, would unnecessarily burden satellites' limited resources, and would vastly reduce the communications capacity of the global satellite network. Instead, a harmonious balance needs to be sought between a satellite's technological and computational capabilities, and the source, volume, and value of the data that it is asked to handle. Only by achieving such a balance can the maximum utility of a satellite be realized.

4. PIRATE DECRYPTION OF SATELLITE TRANSMISSIONS

As a general rule, it is reasonable to assume that encrypted satellite messages contain content that is important or valuable in some way. After all, why would a sender go to the trouble of encrypting a message if its contents were not of value? Unfortunately, the fact that encrypted satellite transmissions contain valuable information is sufficient motivation for some individuals, organizations, and governments to attempt to decrypt and benefit from such information, even if they are not its intended recipients. In the world of encrypted satellite communications, this problem of pirate signal decryption is compounded by two additional factors. First, the dispersive nature of satellite-to-ground transmissions — as illustrated in Figure 38.2 — creates an environment in which many people other than the intended recipient have access to the encrypted signal. This is, of course, also one of the great benefits of satellite communication, since it allows providers of commercial services such as satellite-based television and radio to ensure that their signals are available to as many potential customers as possible. Second, equipment designed to receive satellite signals is, at least in the developed world, both abundant and relatively inexpensive.

As opposed to satellite *transmitters* or *transceivers* — both of which can send messages to satellites — the vast majority of the satellite communications devices in use today are classified simply as *receivers*, which can receive satellite transmissions but cannot send them. These differences are illustrated in Figure 38.6 below.

There are literally hundreds of millions of GPS devices, commercial satellite television receivers, and satellite radio devices in use in the world today, and while all are designed to receive satellite signals, only a tiny fraction can actually send them. When viewed through the eyes of a signal pirate, the combination of these

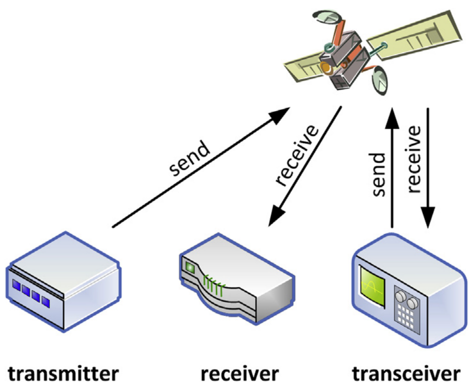

FIGURE 38.6 Communications capabilities of satellite transmitters, receivers, and transceivers.

factors makes encrypted satellite transmissions a very tempting target. There are three reasons for this: First, since the encrypted signal is already available, no additional effort (such as physical wiretapping) is required in order to gain access to the signal itself. Second, since compatible receiving equipment is relatively inexpensive and widely available, acquiring the equipment necessary to receive an encrypted satellite signal is not at all difficult for most would-be pirates. Finally, although pirating encrypted satellite transmissions is illegal in many countries, the fact that most satellite communications devices are simple receivers that cannot transmit any information back to the sender means that the probability of a signal pirate being detected and subsequently punished is quite low.

Since signal piracy has become a rampant phenomenon in the realm of commercial satellite communications, a survey of the history of satellite signal piracy should prove useful. As described earlier in this chapter, modern digital satellite communication relies on keyed encryption algorithms for message security. In this model, the sender first encodes a message by running the digital data through an encryption algorithm with a chosen key. The resulting encrypted data are then relayed to the receiver by way of a satellite transmission, after which the receiver can decrypt the message using the appropriate key. Anyone wishing to access the encrypted satellite transmission must therefore satisfy three conditions if he or she is to be successful. First, the receiver must have access to the encrypted signal. This typically means that the receiver must possess compatible receiving equipment, and must be geographically located within the satellite's signal dispersion zone. Next, the receiver must know which encryption algorithm was used to encode the message. This is usually not a significant problem, since the encryption algorithm is typically embedded within the hardware or software of the receiving device. Finally, presuming that the first two conditions have been met, the receiver must apply the proper key in order to unlock the encrypted digital message. It is toward this final condition that efforts aimed at signal piracy are most often directed.

Circuit-based Security

Since most satellite receivers are not capable of two-way communication, they are also generally not capable of negotiating a new key with the sender of the encrypted message in real-time. The sender of the message must therefore find some other way of supplying its authorized receivers with the proper key, and many different approaches have been developed with this problem in mind. In early secure satellite communications, the means of decoding encrypted transmissions were often built directly into the receiving devices themselves in the form of fixed solid-state circuitry. The "key" in these cases would be the one unique circuit design that would allow a given message to be decrypted. Anyone who owned such a receiver could therefore decode the encrypted transmission, and the sender maintained security by regulating who was given access to compatible receiving devices.

From a security perspective, this early approach was plagued by several obvious flaws. First, anyone able to clone the circuitry of the receiving device would have immediate access to the encrypted message. Circuit components and circuit design knowledge were quite rare in the early days of satellite communication, but it was not long until a would-be signal pirate with a little knowledge could walk into his or her local electronics supply store and buy everything needed to build a simple satellite receiver. Since the security of this approach depended on maintaining the secrecy of the circuit design, the entire system would be compromised as soon as knowledge of that design was made available outside of the circle of authorized recipients. The security of the system could thence only be restored by replacing all of the legitimate receivers with new receivers that contained a different unique circuitry key. If only a few people were authorized to receive the encrypted messages, then replacing the compromised devices might not be terribly problematical. If thousands or even millions of people were authorized to receive the encrypted messages, however, then replacing all of the compromised receivers could be a financially and logistically daunting prospect. Clearly, a better approach was needed.

Removable Security Cards

The next major evolutionary step in secure satellite communications arrived with the introduction of removable security cards. In this model, the receiving devices themselves were of a generalist design inasmuch as they could receive satellite messages encrypted with any number of algorithms or keys. Decoding the encrypted message, however, required that a proprietary security card be inserted into the receiver. It was thus the security card and not the receiver itself which contained the proper circuitry for decrypting the signal. This approach had three major advantages. First, service offerings could be readily stratified into multiple layers. A satellite television customer who wanted to purchase a premium movie channel, for example, could be sent a security card capable of decrypting that channel. Second, the security cards could be rotated according to some predefined schedule. Secret military communications, for example, might use a different security card every day or every week in order to enhance the overall security of the system. Third, if the security of the decryption circuitry were ever compromised, the sender would only need to replace the security

cards themselves. This would, of course, be much less expensive than replacing all of the receivers completely.

Unfortunately, this security card-based approach suffered from many of the same fundamental flaws as earlier approaches. Namely, an aspiring signal pirate could gain access to the encrypted signal simply by cloning the circuitry of the security card. Once successful, the pirate could rest comfortably knowing that the probability he or she would be detected was virtually zero. This problem came to a head when the first several generations of security cards developed by direct broadcast satellite television companies were cracked almost immediately after being released. Not only did this create a great deal of embarrassment and bad press for these companies, but it also spawned a lively and flourishing black market for pirated satellite security cards. Eventually, a new generation of security cards that incorporated what are known as application-specific integrated circuits (ASICs) was released in order to combat this problem. As the name implies, an ASIC is an integrated circuit that is designed for a very specific purpose — in this case, to decode encrypted satellite signals. Since integrated circuits are much smaller than standard circuitry and can contain thousands if not millions of logic gates, reverse-engineering an ASIC's circuit pathways is an extremely difficult task that requires highly specialized equipment such as a circuit probe or an electron microscope. While the introduction of ASICs all but eliminated the black market for cloned satellite security cards, signal piracy is still prevalent today as pirates have found ways of tinkering with or reprogramming existing cards to allow them to illicitly receive premium or restricted content. There is little reason to believe that this long-lived battle between signal pirates and satellite content providers will end anytime soon.

5. SATELLITE ENCRYPTION POLICY

Given the rapid adoption of satellite communications — and the potential security implications associated therewith — many governments and multinational coalitions are increasingly establishing policy instruments with a view toward controlling and regulating the availability and use of satellite encryption in both the public and private sectors. Such policy instruments have wide-reaching economic, political, and cultural implications that commonly extend well beyond national boundaries. One might, for example, consider the export controls placed on satellite encryption technology by the United States government, which many consider to be the most stringent in the world. Broadly, these export controls were established in support of two primary objectives. First, the maintenance of a restrictive export policy allows the government to review and assess the merits of any newly developed satellite encryption technologies that have been proposed for export. If the export of those technologies is ultimately approved, the government will possess a detailed understanding of how the technologies operate, potentially allowing for their encryption schemes to be defeated if deemed necessary. Second, such controls allow the government to prevent satellite encryption technologies of particularly high merit from leaving the country, especially if the utilization of those technologies by foreign entities would interfere with U.S. intelligence-gathering activities. Although these stringent controls may appear to be a legacy of the xenophobic policies of the Cold War, they are nevertheless still seen as prudent measures in a world where information and communication technologies can be readily leveraged to advance extreme agendas. Unfortunately, such controls have potentially negative economic implications, insofar as U.S. firms may be barred from competing in the increasingly lucrative global market for satellite communication technologies.

The establishment and maintenance of satellite encryption policy also needs to be considered in the context of satellite systems of global import. Consider, for example, the NAVSTAR Global Positioning System (GPS), whose constellation of satellites enables anyone with a GPS receiver to accurately determine their current location, time, elevation, velocity, and direction of travel anywhere on or near the surface of the Earth. In recent years, GPS capabilities have been incorporated into the navigational systems of automobiles, ocean-going vessels, trains, commercial aircraft, military vehicles, and many other forms of transit all over the world. Despite its worldwide use, the NAVSTAR GPS satellites are currently operated by the 2nd Space Operations Squadron of the United States Air Force, implying that satellite encryption policy decisions related to the GPS system are controlled by the U.S. Department of Defense. One of the options available to the United States government through this arrangement is the ability to selectively or entirely block the transmission of civilian GPS signals, while retaining access to GPS signals for military purposes. Additionally, the United States government reserves the right to introduce errors into civilian GPS signals, thus making them less accurate. Since the U.S. government exercises exclusive control over the GPS system, users all over the world are forced to place a great deal of trust in the goodwill of its operators, and in the integrity of the encryption scheme for the NAVSTAR uplink channel. Given the widespread use of GPS navigation, a global catastrophe could ensue if the encryption scheme used to control the NAVSTAR GPS satellites were to be compromised. Because the GPS system is controlled by the U.S. military, the resiliency and security of this encryption scheme cannot be independently evaluated.

In the reality of a rapidly globalizing and interconnected world, the effectiveness of national satellite encryption policy efforts may not be sustainable in the long run. Satellite encryption policies face the same legal difficulties as so many other intrinsically international issues; to wit, outside of international agreements, the ability of a specific country to enforce its laws extends only so far as its geographic boundaries. This problem is particularly relevant in the context of satellite communications, since the satellites themselves orbit the Earth, and hence do not lie within the geographic boundaries of any one nation. Considered in conjunction with the growing need of governments to share intelligence resources and information with their allies, future efforts targeted toward satellite encryption policy-making may increasingly fall under the auspices of international organizations and multinational coalitions.

Finally, let's briefly look at Satellite Encryption Service (SES). SES provides dedicated and reliable satellite encryption based transmission for specific data networks and mission critical applications, where landline access may not be available; as well as, wideband video broadcast transmission. The connection from the satellite earth station to the Service Delivery Platform (SDP) is included in this service.

6. SATELLITE ENCRYPTION SERVICE

Satellite Encryption Service can be used as dedicated transmission service for voice, data, and video traffic transmission and wideband broadcast applications, such as broadband distance learning and broadcast of data/multimedia files. The service provides full-duplex, half-duplex, and simplex (broadcast) encrypted transmissions using C-band, Ku-band, and Ka-band satellites.

SES provides dedicated and ad-hoc (reservation-based) encrypted satellite transmission. This transmission can be used by any application services at a customer specified bandwidth between two or more distance learning, broadcast quality National Television System Committee (NTSC) video and associated audio, digital compressed video and associated audio, including encrypted communications specified end points. The connection between the locations receiving this encryption service is permanently established unless a service request for modification, move, or disconnect is received.

This encryption service can be used for applications such as voice, data, video, and multimedia; and, may include Government end-to-end encrypted communications. As previously stated, SES also provides reservation based wideband encrypted satellite broadcast transmission that can be used for numerous applications.

SES connects to and interoperates with specified permanent or temporary locations (SDPs, such as PBX, Multiplexer, router, video codec, earth station, and VSAT (fixed and transportable/deployable)). This results in a satellite encryption strategy being guided by a set of pre-cutover activities (see checklist: "An Agenda For Action For SES Pre-cutover Activities").

An Agenda for Action for SES Pre-Cutover Activities

In order to provide timely, comprehensive, relevant, and accurate satellite encryption strategy, the following set of pre-cutover activities must be adhered to (check all tasks completed):

Administrative

_____**1.** Has a Hierarchy Code (HC) been provided to the vendor?

_____**2.** Have Local Contacts (recommend at least two per location) been identified and contact information provided?

_____**3.** Has a Project Specific Transition Plan Identifier been assigned?

_____**4.** Note (P_OPS) in the Service Request Number (SRN) if this is parallel encryption service.

Pre-Ordering/Design Decisions

_____**5.** Has the vendor developed the functional and performance specifications for Satellite Encryption Service (SES) systems and Sensor Evolutionary Developments (SEDs) in accordance with requirements? This task will include the development of the operational concept for SES within the overall network architecture.

_____**6.** Has the vendor identified all necessary interfaces between the wireline and wireless systems and SES?

_____**7.** Has the vendor defined the contours of the SES coverage to make and receive calls?

_____**8.** Has the vendor presented a plan to continue to provide any changes to satellite footprints for each satellite system providing the coverage?

_____**9.** Determine the Parallel Operations Period – all orders for parallel service will have to be so noted in the Service Request Number (SRN).

_____**10.** Fall-Back plan: Has the vendor provided a detailed fall-back/back-out plan to all stakeholders?

Site Preparation

_____**11.** Has the vendor conducted site surveys at all locations if required and provided site survey reports?

_____**12.** Has the vendor delivered an acceptable, detailed, system design? This design plan, at a minimum,

will address network topology, configuration, addressing (fleet mapping), coverage, availability, reliability, scalability, security, Service Enabling Devices (SEDs), and disaster recovery requirements.

User Training

_____**13.** Has the vendor provided any required training and documentation for users?

Installation

_____**14.** Has the vendor managed the SEDs required for the installation and operation of the SES to include ensuring that SEDs are transported to the appropriate site of deployment and/or stored until installation is complete?

Network Management

_____**15.** Has the vendor submitted a detailed, overall management plan for the SES to include operational support?

Documentation

_____**16.** Has the vendor provided all required documentation (Systems Specifications Document, System Design Document, and Test Documentation when completed)?

Execute Tests

_____**17.** Have the Network Management Organization and vendor reviewed the results of this testing to insure all is ready for the actual cutover?

_____**18.** Conduct pre-cutover testing

7. THE FUTURE OF SATELLITE ENCRYPTION

Despite the many challenges faced by satellite encryption, the potential advantages afforded by satellites to mankind are so tantalizing and alluring that the utilization of satellite-based communication can only be expected to grow for the foreseeable future. As globalization continues its indefatigable march across the terrestrial surface, access to secure, high-speed communications will be needed from even the most remote and sparsely populated corners of the globe. Satellites by their very nature are well-positioned to meet this demand, and will therefore play a pivotal role in interconnecting humanity and enabling the forthcoming global Information Society. Furthermore, recent developments in the area of quantum cryptography promise to further improve the security of satellite-based encryption. This rapidly advancing technology allows the quantum state of photons to be manipulated in such a way that the photons themselves can carry a synchronous cryptographic key. The parties involved in a secure communication can be certain that the cryptographic key has not been intercepted, because eavesdropping upon the key would introduce detectable quantum anomalies into the photonic transmission. By using a constellation of satellites in low earth orbit, synchronous cryptographic keys could be securely distributed via photons to parties wishing to communicate, thus resolving the key exchange problem. The parties could then establish secure communications using more traditional satellite channels. The further development and adoption of technologies such as quantum cryptography ensures that satellite-based communication has a bright — and secure — future.

There are, of course, risks to relying heavily on satellite-based communication. Specifically, if the ability to access critical satellite systems fails due to interference or damage to the satellite, disastrous consequences may ensue. What might happen, for example, if interference from a solar flare were to disrupt the constellation of global positioning satellites? What might happen if a micrometeoroid storm were to damage all of the weather satellites monitoring the progress of a major hurricane? What might happen to a nation's ability to make war if anti-satellite weapons were deployed to destroy its military communications and intelligence-gathering satellites? Questions such as these highlight the risks of relying too heavily on artificial satellites. Nevertheless, as the costs associated with building, launching, and operating satellites continue to decline, the utilization of satellite technology will, for the foreseeable future, become an increasingly common part of the human experience.

8. SUMMARY

This chapter focused on encrypted satellite data transmissions (uplink and downlink) in the critical national infrastructure and private industry. Over the last 16 years, the Federal Government and corporations, have become increasingly reliant on the commercial satellite communications industry. Today, the satellite industry is providing encrypted voice, data, and video services in support of Government and commercial operations, including national security and emergency preparedness (NS/EP) missions. The commercial industry is also supplying the majority of the encrypted satellite communications used for military and surveillance operations along and outside the border of Iran and within Afghanistan. As part of the critical national infrastructure, encrypted satellite networks provide unparalleled coverage of remote geographical areas and difficult terrain. They complement

terrestrial networks also used to provide NS/EP communications support.

The terrestrial components of encrypted satellite networks contain many of the same subsystems found in other communications networks. As a result, encrypted satellite and terrestrial networks share similar cyber vulnerabilities and mitigation measures. However, because satellites must be controlled remotely from Earth, satellite operators take special care to mitigate two risks: (1) remote introduction of a false spacecraft command; and (2) a malicious third party preventing the spacecraft from executing authorized commands or interfering with satellite telemetry reception.

Satellite operators use redundant and geographically diverse facilities to protect terrestrial infrastructure from man-made and natural threats and to ensure continuity of encrypted critical satellite network functions. Ground stations are connected by redundant, path-diverse, cryptographically secured communications links and employ preventative measures such as buffer zones and robust security systems to protect from attack. Further, operators maintain personnel security procedures, including background checks, employee badges, logged entry and exit, and on-site security guards, as part of their best practice security efforts.

Consistent with Government policy, most satellite companies use the National Security Agency-approved satellite command uplink encryption for satellites supporting U.S. Government services. As operators replace their older, legacy satellites that are technically incapable of encrypting commands, newer satellites are likely to be fully compliant with the Government's policy direction.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Depending on the type of satellite communications link that needs to be established, substantially different technologies, frequencies, and data encryption techniques may be required in order to secure a satellite-based communications channel.
2. True or False? For purposes of simplicity, the value of transmitted information can be classified along three dimensions: high-value, medium value and low-value.
3. True or False? One of the problems common to all forms of satellite encryption relates to signal degradation.
4. True or False? Protecting a transmission that is being sent to a satellite from at or near the surface of the Earth requires much more than just cryptographic techniques; to wit, encrypting the message itself is a necessary but insufficient condition for protecting the transmission.
5. True or False? Before a signal is sent to the terrestrial surface, it may need to be transmitted across an extra-planetary link.

Multiple Choice

1. For communications purposes, modern satellites can be classified into two categories:
   A. Type 1
   B. Type 2
   C. Type 3
   D. Type 4
   E. Type 5
2. Any satellite-based communication can be classified into one of:
   A. Two possible categories
   B. Six possible categories
   C. Four possible categories
   D. Eight possible categories
   E. Seven possible categories
3. In addition to the risk of interception, asynchronously keyed encryption algorithms are typically at least:
   A. 10,000 times slower than synchronously keyed encryption algorithms
   B. 20,000 times slower than synchronously keyed encryption algorithms
   C. 30,000 times slower than synchronously keyed encryption algorithms
   D. 40,000 times slower than synchronously keyed encryption algorithms
   E. 50,000 times slower than synchronously keyed encryption algorithms
4. As opposed to satellite *transmitters* or *transceivers* — both of which can send messages to satellites — the vast majority of the satellite communications devices in use today are classified simply as:
   A. Devices
   B. Signals
   C. Transmissions
   D. Receivers
   E. Messages
5. What is an integrated circuit that is designed for a very specific purpose:
   A. ASIC
   B. NAVSTAR
   C. GPS
   D. SES
   E. SDP

EXERCISE

Problem

How would you go about breaking the encryption algorithms known as A5-GMR-1 and A5-GMR-2 that are used to secure civilian communications between mobile phones and satellites based on the GMR-1 and GMR-2 satphone standards?

Hands-On Projects

Project

Finding the right satellite encryption solution is critical for financial services providers in order to meet compliance requirements. A bank needed a cost-effective, secure and reliable way to back up its data files, and faced a decision between choosing a hardware solution or finding the right software that would work on their system. What motivated the bank's search for a satellite encryption solution and what approach did it take to find that solution?

Case Projects

Problem

This case study illustrates a need for a new satellite receiver platform with a unique encryption system. Please identify what type of platform should be developed.

Optional Team Case Project

Problem

A commercial satellite encryption communications solutions and hardware company had run into major impediments on both cost and delivery. Please identify how the company redesigned their commercial grade satellite receiver to achieve an increase in delivery at a reduced cost.

1. ABSTRACT

This chapter will explain the cryptographic background that forms the foundation of PKI systems, the mechanics of the X.509 PKI system (as elaborated by the Internet Engineering Task Force), the practical issues surrounding the implementation of PKI systems, a number of alternative PKI standards, and alternative cryptographic strategies for solving the problem of secure public key distribution. PKI systems are complex objects that have proven to be difficult to implement properly. This chapter aims to survey the basic architecture of PKI systems, and some of the mechanisms used to implement them. It does not aim to be a comprehensive guide to all PKI standards or to contain sufficient technical detail to allow implementation of a PKI system. These systems are continually evolving, and the reader interested in building or operating a PKI is advised to consult the current work of standards bodies referenced in this chapter.

2. CONTENTS

1. **Cryptographic Background**
   - Digital Signatures
   - Public Key Encryption
2. **Overview of PKI**
3. **The X.509 Model**
   - The History of X.509
   - The X.509 Certificate Model
4. **X.509 Implementation Architectures**
5. **X.509 Certificate Validation**
   - Validation Step 1: Construct the chain and validate signatures
   - Step 2: Check validity dates, policy and key usage
   - Step 3: Consult revocation authorities
6. **X.509 Certificate Revocation**
   - Online Certificate Status Protocol
7. **Server-based Certificate Validity Protocol**
8. **X.509 Bridge Certification Systems**
   - Mesh PKIs and Bridge CAs
9. **X.509 Certificate Format**
   - X.509 V1 and V2 format
   - X.509 V3 format
   - X.509 Certificate Extensions
   - Policy Extensions
   - Certificate Policy

1. INTRODUCTION TO KEY EXCHANGE

What Are Key Exchange Protocols?

One of the main goals of cryptography is to provide secure communication channels between different parties. Security here means various flavors of data secrecy, message integrity, and communicant authenticity. One way to construct secure channels between parties is for them to share suitable *keys* that they keep secret and use as input to encryption and message authentication algorithms. Roughly, keys deemed suitable for such cryptographic applications are required to be *long* (e.g. from one hundred to several hundreds of bits, depending on the application and desired level of security) and *random*. This basically guarantees that they cannot be predicted or exhaustively searched for in a reasonable amount of time. We are now faced with the question of establishing keys over an insecure network. Key exchange protocols are meant to provide an answer. More formally, a key exchange protocol is a cryptographic procedure in which two or more entities exchange messages to jointly determine a strong cryptographic key that cannot be computed by outsiders [1].

One may wonder whether there is a vicious circle here, since the problem of exchanging keys over an insecure network can be viewed as a particular case of secure message transmission. The point is that the successful exchange of a single key can lead to efficiently securing much larger amounts of data. Typically, a fresh key is established for each new conversation in which the parties may want to engage; such conversations are called sessions, and the keys used to secure them are called session keys.

The Historic Example: The Diffie-Hellman Key Exchange

In 1976, Whitfield Diffie and Martin Hellman proposed a method for creating session keys over an insecure channel [2]. Suppose Alice $\mathcal{A}$ and Bob $\mathcal{B}$ wish to share a key. We assume that they share the following public information: the description of a large integer n, a cyclic group G of order n, and a generator g for G. (See part IV, *Encryption Technology*, Chapter 37, *Data Encryption*, in the sequel, for basic definitions of groups, generators, etc.) We will briefly address the security of the public data later; what is important to note for now is that potential adversaries know it as well.

The *Diffie-Hellman Key Exchange* runs as follows:

- $\mathcal{A}$ chooses $x \in \mathbb{Z}_n$ randomly, computes $X := g^x$, and sends X to $\mathcal{B}$. x is kept secret;
- Upon receiving X, $\mathcal{B}$ chooses $y \in \mathbb{Z}_n$ randomly, computes $Y := g^y$, and sends Y back to $\mathcal{A}$. He computes $K_{\mathcal{B}} := X^y$, and keeps y secret;
- Finally, upon receiving Y, $\mathcal{A}$ computes $K_{\mathcal{A}} := Y^x$.

The properties of cyclic groups (see Chapter 37) ensure that $K_{\mathcal{A}} = K_{\mathcal{B}} = g^{xy}$. Thus, $\mathcal{A}$ and $\mathcal{B}$ end up sharing

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00040-4

$\mathcal{A}$		$\mathcal{B}$
x		y
	$\xrightarrow{X:=g^x}$	
	$\xleftarrow{Y:=g^y}$	
$K_{\mathcal{A}} := Y^x$		$K_{\mathcal{B}} := X^y$

FIGURE 40.1 Diffie-Hellman key exchange.

the same group value, from which a session key can be derived. We now turn to explaining why this is (the starting point to) an appropriate solution.

The **secrecy** of the key is based on the observation that for well-chosen n, computing g^{xy} knowing only the tuple (n, G, g, g^x, g^y) appears to be infeasible in a reasonable amount of time, provided x and y are chosen sufficiently randomly.[1] This is known as the *Computational Diffie-Hellman Assumption* (CDH). It is widely believed that, for many concrete groups, the assumption indeed holds. (Examples of such groups will appear in section 3 of this chapter.) Note that CDH is related to the difficulty of the *Discrete Logarithm Problem* (DLP) where for randomly chosen x, computing x knowing only g and g^x is difficult.

In fact, in some groups it is widely believed that the *Decisional Diffie-Hellman Assumption* (DDH) holds: If x, y, and z are chosen sufficiently randomly, there is no efficient statistical test that can tell apart $(n, G, g, g^x, g^y, g^{xy})$ and (n, G, g, g^x, g^y, g^z). This basically means that g^{xy} appears truly random even given g^x and g^y. This implies that the protocol in Figure 40.1 will achieve the required **randomness** property of the key g^{xy}. However, in practice it is more common to compute the key as a *function of* g^{xy}; often, a *cryptographic hash function* is used. (See Chapter 37 for basic properties of cryptographic hash functions.) One reason to do this is to obtain a key of correct length for higher-level applications. This function needs to have special properties to guarantee that the key ultimately computed remains random.[2] Finally, n being a large number, g^{xy} is a large value, making it relatively easy to derive **long** keys from it.

We point out that a huge amount of key exchange protocols still use the Diffie-Hellman construct as a basis for computing secret keys. (In fact, all three protocols described at the end of this chapter use it in one way or another.) The main issue at hand now is authenticating the exchange.

1. Strictly speaking, these values need to be chosen *uniformly at random*. In practice, they are computed by *pseudo-random number generators*. Also, n is often required to be of special form.
2. In case only the CDH assumption holds, this additional step is vital for security.

Authentication

Using the classic protocol in the preceding, we illustrate the main problem that arises when one does not pay attention to the authenticity of the key exchange itself. That would be the protocol's vulnerability to *active* attacks.

Man in the Middle

In addition to $\mathcal{A}$ and $\mathcal{B}$, let $\mathcal{M}$ be a malicious adversary intercepting communications between $\mathcal{A}$ and $\mathcal{B}$. By impersonating $\mathcal{A}$ to $\mathcal{B}$ and vice versa, and injecting her own messages in the protocol flow, $\mathcal{M}$ can fool $\mathcal{A}$ and $\mathcal{B}$ into thinking they are communicating with each other, while in fact they are both communicating with $\mathcal{M}$. The attack runs as follows (see Figure 40.2):

- $\mathcal{M}$ intercepts $\mathcal{A}$'s first message to $\mathcal{B}$, that is $X = g^x$. She chooses some value u and sends instead $U := g^u$ to $\mathcal{B}$, claiming it is from $\mathcal{A}$.
- $\mathcal{B}$ selects y, computes $Y = g^y$, and sends Y back to $\mathcal{A}$. $\mathcal{B}$ also computes what it thinks is the correct Diffie-Hellman value, $U^y = g^{uy}$.
- $\mathcal{M}$ intercepts Y, and instead computes $V := g^v$ for some value v, which it returns to $\mathcal{A}$. $\mathcal{A}$ thus computes $V^x = g^{vx}$.
- $\mathcal{M}$ now computes $X^v = g^{vx}$ and $Y^u = g^{uy}$. It shares the former value with $\mathcal{A}$, the latter value with $\mathcal{B}$, and can now begin a falsified session with both parties, impersonating each to the other.

This is called a *man-in-the-middle* attack; its success is due to the absence of any mechanism authenticating the message flow between $\mathcal{A}$ and $\mathcal{B}$. In other words, in the basic Diffie-Hellman protocol described above, neither party really knows whether or not the message it received is indeed from whom it claims to be.

Implicit and Explicit Authentication

Essentially two flavors of authentication can be provided by a key exchange protocol. We say that *implicit authentication* is reached if after completing its role in a protocol run, a party is guaranteed that if it has not conversed with the intended partner, whomever it really has communicated with will fail at computing the same session key. *Explicit authentication* is reached if, after completing its role in a protocol run, a party obtains the guarantee that it was speaking to its intended partner, and that this partner has computed the correct session key.

The latter of these two notions is more desirable than the former because the honest party can start using the computed session key in a higher application knowing that its intended partner can actually participate, whereas if the exchange is implicitly authenticated, it may very well be that the honest party will open a session alone.

Often, implicitly authenticated protocols are converted into explicitly authenticated ones with a mechanism known as *key confirmation*, in which an honest party is guaranteed that its intended partner indeed did compute the correct session key. These considerations will appear again in section 2 of this chapter.

Examples of how to construct authenticated key exchange schemes are described below. For *any* such scheme to work, *some form of secret, long-term keying information must be in place for both parties*.

Classical Key Exchange

In what is considered classical key exchange, the long-term keying material that a user is required to possess is usually one of two kinds: (i) a cryptographically secure key for a symmetric cryptographic algorithm (e.g. a 128-bit AES encryption key, see Chapter 37) or (ii) a cryptographically secure public key/secret key pair for an asymmetric cryptographic algorithm (e.g., a 1024-bit RSA modulus, and appropriate encryption and decryption exponents e and d; see Chapter 37). In the former case, the long-term key needs to be also known to the other party; for key management purposes, it is actually more convenient to have the users share their respective keys with a trusted server, which will then aid those users and their target desired partners in the network to establish session keys between themselves. In the latter case, the public key is what the other party will use, and a trusted *Certificate Authority* (CA) will ensure that this key is indeed bound to the user it is purportedly associated with via a *Certificate* in a *Public Key Infrastructure* (PKI). (See Chapter 37 for a general introduction to PKI.)

In the paragraphs that follow, we give an overview of the symmetric-key Needham-Schroeder key exchange protocol and the PKI-based Station-to-Station key exchange protocol (see Figures 40.3 and 40.4).

Long-term Symmetric Keys

The symmetric-key Needham-Schroeder key establishment protocol, which is the main building block of the popular Kerberos system, was first proposed in 1978 [4] and slightly modified in 1987 [5]. In addition to the two parties $\mathcal{A}$ and $\mathcal{B}$, there is a trusted server $\mathcal{T}$. $\mathcal{A}$ (resp., $\mathcal{B}$) shares a secret long symmetric key $K_{\mathcal{AT}}$ (resp., $K_{\mathcal{BT}}$) with $\mathcal{T}$. The protocol we shall describe now is the original version from [4] (see Figure 40.3).

Let E denote a symmetric-key encryption algorithm; for any key K, E_K is the encryption function obtained from E under key K. Also, M and N will be used to designate *nonces*. (A *NONCE* is a *N*umber used *ONCE*. Here, they are strings of some agreed upon length picked randomly.) The protocol runs as follows:

- $\mathcal{A}$ sends $ID_{\mathcal{A}}$, $ID_{\mathcal{B}}$, $N_{\mathcal{A}}$, to $\mathcal{T}$, where $N_{\mathcal{A}}$ is a nonce she picked randomly;

$\mathcal{A}$		$\mathcal{M}$		$\mathcal{B}$
x		(u, v)		y
	$\xrightarrow{X:=g^x}$		$\xleftarrow{Y:=g^y}$	
		$U := g^u$	$\xrightarrow{U}$	
	$\xleftarrow{V}$	$V := g^v$

FIGURE 40.4 Station-To-Station [3].

- $\mathcal{T}$ computes $E_{K_{\mathcal{AT}}}(N_{\mathcal{A}}, K_{\mathcal{AB}}, ID_{\mathcal{B}}, E_{K_{\mathcal{BT}}}(K_{\mathcal{AB}}, ID_{\mathcal{A}}))$ and sends it back to $\mathcal{A}$, where $K_{\mathcal{AB}}$ is a key $\mathcal{T}$ chooses randomly for $\mathcal{A}$ and $\mathcal{B}$. $K_{\mathcal{AB}}$ will be the session key;
- $\mathcal{A}$ decrypts the message received and checks that the identity of her intended partner is correct and that the nonce $N_{\mathcal{A}}$ is the one picked previously. If any checks fail, the protocol is aborted. Otherwise, she sends $E_{K_{\mathcal{BT}}}(K_{\mathcal{AB}}, ID_{\mathcal{A}})$ to $\mathcal{B}$;
- $\mathcal{B}$ decrypts the received message and discovers the identity of his intended partner $ID_{\mathcal{A}}$. $\mathcal{B}$ computes $E_{K_{\mathcal{AB}}}(ID_{\mathcal{A}}, N_{\mathcal{B}})$ and sends it to $\mathcal{A}$, where $N_{\mathcal{B}}$ is a nonce generated randomly;
- $\mathcal{A}$ decrypts the message received using key $K_{\mathcal{AB}}$, and checks to see if the identity is correct. If it is, she computes $E_{K_{\mathcal{AB}}}(N_{\mathcal{B}} - 1)$, and sends it to $\mathcal{B}$;
- Finally, $\mathcal{B}$ decrypts the last message received using key $K_{\mathcal{AB}}$, and checks to see if the decrypted value is indeed equal to $N_{\mathcal{B}} - 1$.

The protocol seems complex, but the underlying authentication mechanism that is exploited throughout is essentially this: When one entity, say $\mathcal{A}$, encrypts a string (m, N), where m is some message and N is a nonce that $\mathcal{A}$ chose randomly, and that nonce is returned to $\mathcal{A}$ subsequently, then $\mathcal{A}$ has the proof that the nonce N and message m were indeed decrypted by the correct entity. Thus, $\mathcal{A}$ can safely continue participating in the protocol. In contrast, if the returned value of the nonce is not what is expected, the protocol is abandoned. Using randomly chosen nonces from one exchange to the next associates unique numbers to each exchange. This keeps a man in the middle from replaying stale data from previous unrelated exchanges. Also, incorporating identities in the clear (and in the encryptions) prevents the adversary from trying to transmit messages to unintended recipients. Finally, notice that the last two flows are composed of encryptions under the session key $K_{\mathcal{AB}}$. This is used to prove to each party that the other actually possesses the right key. We shall return to this important property later.

Relying on Public-Key Infrastructure

Another type of preestablished long-term keying material that can be used is *certified public key/secret key pairs*. This requires a trusted CA to *digitally sign* messages binding parties' identities to their public keying material. These signed messages are known as *certificates*. Let pk_{CA} and sk_{CA} be the CA's public verification and private signature keys respectively. (See Chapter 37 for information on digital signatures.) The certificate of a given party will also contain descriptions of the instantiated mathematical objects used in the public-key algorithms. Let $Cert_{\mathcal{A}}$ (resp., $Cert_{\mathcal{B}}$) denote $\mathcal{A}$'s (resp., $\mathcal{B}$'s) certificate. Below we describe the main flows of the well-known Station-To-Station protocol (STS; see [3]). Let G be a cyclic group of order denote n in which DDH is believed to hold, g be a generator for G, E be a symmetric encryption algorithm, and S be the signature algorithm of a digital signature scheme. (See Chapter 37.) The protocol runs as follows:

- $\mathcal{A}$ sends to $\mathcal{B}$ the data $Cert_{\mathcal{A}}$ and g^x, where x is chosen at random, and $Cert_{\mathcal{A}}$ contains the group parameters and a description of E. It also contains $\mathcal{A}$'s public signature verification key, $pk_{\mathcal{A}}$;
- $\mathcal{B}$ first verifies the CA's signature on $Cert_{\mathcal{A}}$ using CA's public key pk_{CA}. If this check fails, $\mathcal{B}$ aborts the protocol. Otherwise, he replies to $\mathcal{A}$ with $Cert_{\mathcal{B}}$, g^y, $c_{\mathcal{B}} := E_K(S_{sk_{\mathcal{B}}}(g^y, g^x))$, where y is chosen at random, $\mathcal{B}$ computes $K = g^{xy}$, $S_{sk_{\mathcal{B}}}(g^y, g^x)$ is a digital signature under key $sk_{\mathcal{B}}$ of (g^y, g^x), and finally $c_{\mathcal{B}}$ is an encryption of the signature under K;
- $\mathcal{A}$ checks the CA's signature on $Cert_{\mathcal{B}}$ using $pk_{\mathcal{A}}$. If this check fails, the protocol is aborted. Otherwise, she computes $K := g^{xy}$ and decrypts $c_{\mathcal{B}}$ using K to obtain $S_{sk_{\mathcal{B}}}(g^y, g^x)$. She verifies this signature on message (g^y, g^x) using $pk_{\mathcal{B}}$. If this check fails, the protocol is aborted. Otherwise, she computes a signature $S_{sk_{\mathcal{A}}}(g^x, g^y)$ on (g^x, g^y) using her private signing key $sk_{\mathcal{A}}$, and then computes an encryption $c_{\mathcal{A}} := E_K(S_{sk_{\mathcal{A}}}(g^x, g^y))$ that she sends back to $\mathcal{B}$;
- Finally, $\mathcal{B}$ decrypts $c_{\mathcal{A}}$ using K and verifies the obtained signature using $\mathcal{A}$'s public verification key $pk_{\mathcal{A}}$. The session key is set to being $K = g^{xy}$.

In this scheme, the authentication is basically provided by the digital signatures. A party is certain that a message was indeed signed by another entity if the signature verification equation under that entity's public key holds. The CA's role is to make sure that an adversary cannot simply replace an honest party's public key with her own in a certificate, since this would require forging a signature under the CA's key. Also, similarly to the Needham-Schroeder protocol, the values g^x and g^y can be viewed as numbers that, in addition to computing a joint session key, serve as unique identifiers for the key exchange, in order to prevent replay attacks. Notice also that the session key K is actually used in the protocol to encrypt the signatures, allowing the parties to demonstrate to one another that they have computed the correct session key.

2. PASSWORD-AUTHENTICATED KEY EXCHANGE

The Need for User-Friendly, Password-Based Solutions

All of the methods described so far have a common property: Whether the long-term keying material is symmetric and shared by both users, or asymmetric and certified using a PKI, keys are long and difficult to use in common applications. One could argue that this information could be embedded in security tokens that users could carry such as smartcards, USB security tokens, and so on. However, this requires additional hardware that will certainly have a cost. It may also introduce compatibility issues in cases when the tokens need to be plugged into another device. Finally, such tokens can always be compromised through loss or theft.

Another method that has been considered to authenticate users involves using human *biometrics*. While such data is indeed unique to the user and—in a certain sense—unforgettable, its use raises many other issues, such as privacy considerations or variability of readings. A further drawback is that biometrics cannot be replaced in case of compromise. The necessary hardware to put in place is also quite expensive.

Nowadays, the most common form of authentication in use is via knowledge of passwords. Passwords are cheap and convenient. They are easy to choose, use, and change when needed, and they are typically human-memorable. The pervasiveness of this method of authentication is the main motivation behind research in *Password-Authenticated Key Exchange* (PAKE).

The objective of a PAKE protocol is to perform an authenticated key exchange like those described above, but assuming that the long-term keying material is **just a password that both parties involved share**.[3] Such a scheme combines the effectiveness of key exchange in producing cryptographically strong session keys with the convenience of authenticating oneself by demonstrating knowledge of a simple password.

However, convenience is often accompanied by security degradation in cryptography; using passwords instead of strong cryptographic keys is no exception and brings forth some important issues that we try to explain in the following sections.

New Security Threats

Using passwords rather than long, cryptographically strong keys to authenticate key exchange protocol flows is not straightforward. For instance, a password cannot just replace a strong symmetric key as input to a classical key exchange protocol. There are mainly two reasons for this.

First for all, passwords are low-entropy data. This makes them vulnerable to *dictionary attacks*, which are essentially brute-force guessing attacks. Second, passwords are quite often mismanaged (e.g., written down or used across several applications). This frequently leads to password compromise, which must be taken into account in PAKE design.

Dictionary Attacks

In classical key exchange, exhaustively searching for the correct long-term key can simply not be done feasibly by construction: It is completely random and very long. A password on the other hand is likely to be short and produced with less-than-ideal randomness from a small set of values, making exhaustive search possible. We illustrate the effects of this phenomenon with a "dummy" protocol.

Assume that $\mathcal{A}$ and $\mathcal{B}$ share a password pw and the description of some group G and generator g for G. Further assume that they share the description of some cryptographic hash function H. $\mathcal{A}$ and $\mathcal{B}$ can attempt to engage in the following variant of the Diffie-Hellman key exchange introduced earlier:

- $\mathcal{A}$ first chooses $x \in \mathbb{Z}_n$ randomly and computes g^x and $h := H(pw, g^x, ID_{\mathcal{A}}, ID_{\mathcal{B}})$. By the properties of the function H, the value h binds $\mathcal{A}$'s identity $ID_{\mathcal{A}}$, her target recipient's identity $ID_{\mathcal{B}}$, and her password to her chosen value. It also effectively hides the password. $\mathcal{A}$ sends $(g^x, h, ID_{\mathcal{A}})$ to $\mathcal{B}$;
- Upon receiving h and g^x, $\mathcal{B}$ computes $H(pw, g^x, ID_{\mathcal{A}}, ID_{\mathcal{B}})$ and checks that it equals h. He thus gains assurance that he indeed received the data from $\mathcal{A}$. He now chooses $y \in \mathbb{Z}_n$ randomly, computes $h' := H(pw, g^y, g^x, ID_{\mathcal{A}}, ID_{\mathcal{B}})$, and sends back $(g^y, h', ID_{\mathcal{B}})$. He computes the key g^{xy};
- Finally, $\mathcal{A}$ checks to see if h' is equal to $H(pw, g^y, g^x, ID_{\mathcal{A}}, ID_{\mathcal{B}})$, and if so computes the key g^{xy}.

This protocol is vulnerable to a dictionary attack: An eavesdropper can simply record the first message, $(g^x, h, ID_{\mathcal{A}})$, and test candidate passwords pw' against h. If for some value pw' the adversary obtains $h = H(pw', g^x, ID_{\mathcal{A}}, ID_{\mathcal{B}})$, it is very likely that she has found the password. Note that the password is *never directly revealed in the protocol*.

This kind of attack is arguably the most important one to prevent in PAKE design because an attacker need not be online to perform it. Offline attackers have more time and computational power for the simple

3. There are also variations of this: For instance, one party may hold the password and the other a function of this password. Typically, the function will be a hash function.

reason that they may be impossible to interrupt. Indeed, in the above example it was only necessary for the adversary to record an exchange. From then on, there is no way to interfere with the adversary's behavior. We call such attacks *offline dictionary attacks*. To prevent them, it is necessary that protocol runs leak not a single bit of information on the underlying password, even if the attacker is engaging in the protocol, and injecting her own data by trying to impersonate a party. This has an important consequence for authentication; we will return to this point later.

Online dictionary attacks are active attacks in which the adversary tries to guess the password through successive login attempts: The adversary engages over and over in the protocol, trying out different passwords, and when the opposing party stops aborting, the adversary knows it guessed the right password. It is clear that protocol design cannot prevent this attack from occurring; however, a well-constructed PAKE should only allow one password to be tested per login attempt. From that point on, it is up to the application supporting the protocol to specify how many failed attempts can be tolerated before, for instance, locking the targeted account.

Forward Secrecy and Known Session Keys

A user's password in a PAKE protocol is viewed as a long-term key (i.e., it is expected to be used many times to create random, independent session keys). It obviously plays a role in the computations of session keys' exchange transcripts and may even appear as an argument to the formula producing the session keys themselves. These relationships cannot be ignored.

On the one hand, passwords are notoriously mismanaged data: They are routinely lost, shared (with unintended parties), and used across several applications. This very often leads to the password getting compromised. Once this occurs, there clearly is no way of stopping an adversary with knowledge of the password from impersonating its rightful owner, at least until the breach is discovered. However, the scheme should ensure that despite this breach, past established session keys remain secure. This property is known as *forward secrecy*.

On the other hand, we have the session keys: There are potentially many of them, and there are no restrictions whatsoever concerning their use. This includes of course running them as input to possibly insecure algorithms. Also, session keys are ephemeral data by nature, but disposing of them after they have served their purpose may not be such an easy task in practice. Given all of this, it is wise to assume that whole session keys may actually be compromised during or after their use. Hence, a PAKE should guarantee that such a disclosure does not breach its security. In particular, this must not leak any password information either. This is referred to as the *known-session key security*.

Other Security Properties

Dictionary attacks are specific to PAKE protocols. However, the forward secrecy and known-session key security were actually first considered in classical key exchange and subsequently carried over to the password-based case. It may be tempting to do this with all security properties that can be defined for key exchange in general, but this is not always possible. For instance, resistance to *key compromise impersonation*—in which an adversary who compromised a user's long-term key can then impersonate other parties to that user—is not satisfied by a PAKE: The other holder of the password can always be impersonated to the attacked user.

Another notion of security that is specific to the password-based case is that of *server compromise resistance* (see [6] or [7]). It arises in the following case: when one of the two parties is a server holding a function of the user's password rather than the password itself. Any ordinary PAKE can be easily converted into one that fits this situation by simply hashing the password for instance. (Ordinary PAKEs are sometimes referred to as *balanced* protocols while the server compromise-resistant ones are known as *augmented* PAKEs.) This captures a realistic scenario: One server may hold functions of many different users which open sessions with it to access various resources. Resistance to server compromise then basically states that the server cannot impersonate a user unless it first performs a dictionary attack on the data it holds. Let us mention that this notion has been disputed, essentially because if server data is indeed compromised, it makes no sense to consider the related passwords safe since they are trivially vulnerable to offline searches. In the remainder of this chapter, we concentrate on balanced PAKEs.

Key Confirmation and Authentication in PAKE

We mentioned earlier that resistance to offline dictionary attacks has an effect on authentication; we return to this issue now. As explained earlier, a PAKE protocol transcript cannot be allowed to leak a single bit of information on the password. This implies that no mechanism can be in place to directly ensure at either end of the protocol that the correct password is being used by the other party. For instance, the password cannot satisfy any kind of efficiently verifiable equation, which happens to be the flaw of the dummy protocol in Figure 40.5. In contrast, this is exactly how a digital signature scheme functions, the key

FIGURE 40.6 Encrypted key exchange.

difference again being that the long-term secret is cryptographically strong. This is the method behind STS.

This makes key confirmation the only way to obtain explicit authentication: Both parties are sure that they have been talking to their intended partner if and only if they can determine that they have computed the same session key. This is especially important in the password-based setting because a server cannot tell a failed login attempt from a successful one without explicit authentication. Yet, this obviously needs to be determined before granting or denying the right to opening a session, and in the latter case, incrementing a rejection counter.

3. CONCRETE PROTOCOLS

In this section we describe three concrete PAKEs. We give an overview of their properties, security guarantees, and known flaws. All three protocols require the parties—$\mathcal{A}$ and $\mathcal{B}$—to share the description of a cyclic group G of large order n. Such information can be directly hard-coded into the program specification running the protocol. Of course, $\mathcal{A}$ and $\mathcal{B}$ also share a password pw.

PAKE research mainly began in the early 1990s [8]. Since then, the research community has produced many different protocols. We chose to present the three algorithms below mainly because they are simple to describe, quite efficient, and have been proposed for standardization. Information relative to their industrial and commercial deployment is described later in this chapter.

For each protocol, we begin by describing the heart of the mechanism itself: the protocol flows that contain the information for computing the shared key. We then go on to discuss the security properties and weaknesses. Finally, we give full descriptions of the protocols, or variants thereof, that have been proposed for standardization. In particular, these descriptions also contain various examples of key confirmation procedures.

Encrypted Key Exchange

The first PAKE ever designed was proposed in 1992 by Bellovin and Merrit [8] and is known as Encrypted Key Exchange, or EKE (see Figure 40.6). The authors were the first to tackle the problem of preventing offline dictionary attacks. To describe the main protocol flow, we first need some notation. E will denote a symmetric encryption algorithm, with D the associated decryption algorithm. (See Chapter 37.) We will designate encryption under key k with E_k and the corresponding decryption with D_k. Similarly to the description of the group G, algorithms E and D are hard-coded into the program specification.Concretely, the group G used will be the multiplicative group $\mathbb{Z}_p^*$ of invertible integers modulo some large prime p of the form $p = 2q + 1$ for some prime q. Thus, G is of order $p - 1$. (See Chapter 37.) Let g be a generator of G. It is conjectured that the CDH assumption holds in this case.

The protocol works as follows:

- $\mathcal{A}$ first chooses $x \in \mathbb{Z}_{p-1}$ randomly and computes g^x and $c_{\mathcal{A}} := E_{pw}(g^x)$. She sends $c_{\mathcal{A}}$ to $\mathcal{B}$;
- Upon receiving $c_{\mathcal{A}}$, $\mathcal{B}$ recovers g^x by computing $D_{pw}(c_{\mathcal{A}})$. He now chooses $y \in \mathbb{Z}_{p-1}$ randomly, computes $c_{\mathcal{B}} := E_{pw}(g^y)$, and sends back $c_{\mathcal{B}}$. He computes the key g^{xy};
- Finally, $\mathcal{A}$ recovers g^y by computing $D_{pw}(c_{\mathcal{B}})$, and computes the key g^{xy}.

Security and Efficiency

Security and Efficiency by Design

The main idea behind the dictionary attack resistance of this protocol is that if the data encrypted using algorithm E under key pw is random enough, then verification of the password becomes infeasible. More concretely, if pw' is some other password, the string $D_{pw'}(c_{\mathcal{A}})$ cannot be told apart from g^x because x, and therefore g^x, is random. In theory, this is a very elegant observation, but we shall see below that it is highly nontrivial to implement in practice, an issue we address in the next sections. Online dictionary attacks are essentially prevented by the fact that if the algorithm E is indeed suitable, it should yield different encryption functions for different passwords.

Forward secrecy is argued to hold for a very simple reason: The shared value g^{xy} is completely independent of the password. Indeed, assuming the password has been

discovered, the only information an attacker can get consists of the two values g^x and g^y from which g^{xy} cannot be computed. Similarly, since random numbers are independently generated from one session key to the next, compromise of previous keys does not affect the security of new ones.

In terms of efficiency, the protocol performs quite well. Since it only requires adding (symmetric) encryption and decryption operations at each user's end, it is only slightly more costly than the original Diffie-Hellman protocol. (Of course, the ultimate efficiency of the protocol depends also on how the encryption function is instantiated, but in general symmetric encryption mechanisms are quite efficient.) Since it requires the CDH assumption to hold in the underlying group, it is necessary to have p be at least 1024 bits long. Therefore, the random numbers that should be chosen by each party need to be 1024 bits long as well.

Security in Theory

It should also be mentioned that the security of EKE's main protocol flows has been studied from a purely theoretical point of view [9]. In this work, the protocol and several of its variants have been *proven secure*; that is, a very precise mathematical proof of security was given (we refer to [9] for exact definitions) assuming that the encryption function satisfies some idealized properties. This is methodologically important and theoretically interesting; however, such proofs do not necessarily immediately translate into real-world security guarantees, as demonstrated in the following section.

Flaws

The protocol, as it is defined, can be made vulnerable to dictionary attacks. The main issue is that even if it is a strictly random element of G, g^x is not randomly distributed in E's plaintext space. Concretely, this means that we cannot expect that for every possible candidate password pw', the decryption $D_{pw'}(c_{\mathcal{A}})$ will fall into $\mathbb{Z}_p^*$; therefore, every time such a test fails, a password can be ruled out. It has been shown (see, e.g., [10]) that the password in use can be very quickly determined by observing just a few protocol runs. Such attacks are known as *partition attacks* because from one protocol run to the next, the list of potentially valid passwords is roughly halved.

Bellovin and Merrit had already noticed this in their work introducing EKE [8]. They proposed some countermeasures such as choosing p as close as possible to the next power of 2, or encrypting $g^x + jp$ rather than g^x where jp is added using a nonmodular operation, and j is constructed in a particular way (see [8] for details). Unfortunately, these ad-hoc fixes are not completely satisfactory. As of yet, they have not been adequately modeled so as to systematically measure their contribution to the protocol's security, and it is not clear that they can be. This makes them difficult to analyze precisely. Furthermore, they do not solve the problem completely anyway: The number of strings obtained by decryption that an adversary can gain meaningful information from may be reduced, but it does not drop to zero.

These instantiation issues illustrate the subtlety of defending against dictionary attacks in practice; another example comes from examining the choice of the underlying group itself. Here we have $G = \mathbb{Z}_p^*$ for a prime p. The idea behind this choice is that any bitstring that corresponds to an integer between 1 and $p-1$ is necessarily an element of the group. Hence, if a trial decryption of $c_{\mathcal{A}}$ with some candidate password yields such a bitstring, there is no way to tell if that password was correct or not. On the other hand, other groups commonly used in cryptography are built in such a way that their elements verify special properties; these cannot be used here again because from trial decryptions may result strings that do not verify these properties, indicating that the tested password was not the right one.

These flaws are not captured in the theoretical security studies we mentioned above precisely because the modeling of encryption by an idealized process completely hides problems that may arise with concrete instantiations.

Proposed Standardization

In 2000, Bellare and Rogaway proposed a PAKE protocol based essentially on EKE for IEEE standardization: AuthA [11]. One of the main concerns the authors raise in their work involves instantiating the encryption function. The security flaws discussed above clearly show that this needs to be done very carefully. In particular, there is no straightforward way to directly replace the ideal cipher with a concrete symmetric encryption algorithm. The authors propose to replace the encrypting operation with multiplying the group element by a hash of the password, allowing them to rely on idealizing a hash function rather than an encryption function. This seems less dangerous because hoping that one concrete fixed function looks random enough is viewed as more reasonable than hoping the same of an entire family of functions parameterized by poorly chosen secrets. Also, it is easier to hash into a group than to force a decryption function to map into a group for all possible decryption keys, so using groups other than $\mathbb{Z}_p^*$ is conceivable in this case. For simplicity, we will assume that $G = \mathbb{Z}_p^*$, with p a prime of the form $p = 2q + 1$, where q is a prime as well. As usual, let g be a generator of G, E be the encryption algorithm, and D be the corresponding decryption algorithm. Finally, let H be a hash function. We assume that $\mathcal{A}$ and $\mathcal{B}$ know this data.

AuthA runs as follows:

- $\mathcal{A}$ first chooses $x \in \mathbb{Z}_{p-1}$ randomly and computes g^x and $c_{\mathcal{A}} := E_{pw}(g^x)$. She sends $c_{\mathcal{A}}$ to $\mathcal{B}$;
- Upon receiving $c_{\mathcal{A}}$, $\mathcal{B}$ recovers g^x by computing $D_{pw}(c_{\mathcal{A}})$. He now chooses $y \in \mathbb{Z}_{p-1}$ randomly, computes $c_{\mathcal{B}} := E_{pw}(g^y)$, g^{xy}, $MK := H(g^x, g^y, g^{xy})$ (MK for "Master Key"), $h := H(MK, 1)$, and sends $c_{\mathcal{B}}$ and h to $\mathcal{B}$;
- Upon receiving $c_{\mathcal{B}}$ and h, $\mathcal{A}$ recovers g^y by computing $D_{pw}(c_{\mathcal{B}})$, and computes g^{xy} and $MK := H(g^x, g^y, g^{xy})$. She then checks to see if the value h received is equal to $H(MK, 1)$. If not, the protocol is aborted. Otherwise, she computes $K := H(MK, 0)$, $h' := H(MK, 2)$, accepts the session key to be K, and sends h' back to $\mathcal{B}$;
- Finally, upon receiving h', $\mathcal{B}$ checks to see if this value is equal to $H(MK, 2)$. If not, the protocol is aborted. Otherwise, $\mathcal{B}$ computes $K := H(MK, 0)$, which he accepts as the session key.

AuthA as described above is one of four different possibilities considered by the authors in [11]. We have chosen to describe the one in which there is mutual authentication through an additional key confirmation process. This process is depicted in Figure 40.7. Ignoring the flaws of the encrypted flows for now, we concentrate first on explaining how the key is confirmed using the hash function. (Another example is given in the full version of SPEKE below.) We return afterwards to considerations on the encryption.

Key Confirmation and Mutual Authentication

In the second step, once $\mathcal{B}$ has computed g^{xy}, he also computes a so-called master key MK from g^{xy}. This data, and the properties of the hash function H, will allow him to prove to $\mathcal{A}$ that he has computed the correct key and will also let him verify that $\mathcal{A}$ has done so as well. In the third step of the protocol, $\mathcal{A}$ computes the master key as well. If h_1 is indeed equal to $H(MK, 1)$, $\mathcal{A}$ is assured that both she and the entity that computed h_1 hold the same master key, therefore also the same value g^{xy}, and therefore the same password. Since by assumption only $\mathcal{B}$ should know this password, $\mathcal{A}$ concludes that she is indeed speaking with $\mathcal{B}$, and that $\mathcal{B}$ can compute the same session key. A similar argument can be made on $\mathcal{B}$'s end, with h_2.

On the Security of Hash-and-Multiply Instantiations of the Encryption Process

Since at the heart of AuthA lie the main flows of EKE, it suffers from the same flaws. We return now to examining how E can be instantiated using a hash function rather than a block cipher. Two methods for accomplishing this have been suggested by the authors in [11]. Let H' be a hash function different from H and that maps strings into the group G. For a group element z and a password pw, the encryption of z under key pw can be:

i. $E_{pw}(z) := z.H'(pw)$, or
ii. $E_{pw}(z) := (r, z.H'(pw, r))$ for some randomly chosen string r.

In both formulas, $z.H'$ is the group multiplication of z by H'.

Using this method, we no longer need to rely on idealizing a block cipher to mathematically prove security. However, we still need to rely on idealizing a hash function. While this is viewed as more "realizable" in practice, it still does not guarantee security, and it can be vulnerable to attacks. A thorough theoretical study in idealized models of the security of various variants of AuthA, including ones in which the encryption is instantiated through hash-and-multiply methods, can be found in [12] and [13]. In these works, once again the protocols are proven secure under idealized assumptions. Yet, real-world attacks on these same variants of AuthA, including those in which hashing replaces encrypting, can be found in [14]. They all involve essentially attacking the procedure used for encryption. The authors also propose a possible instantiation of their own for the hash-and-multiply method, but still warn that it may be subject to attack.

$\mathcal{A}$		$\mathcal{B}$
		$MK := H(g^x, g^y, g^{xy})$
	$\xleftarrow{h}$	$h := H(MK, 1)$
$MK := H(g^x, g^y, g^{xy})$

Simple Password Exponential Key Exchange

Another popular protocol that was first proposed in 1996 by Jablon [15] is Simple Password Exponential Key Exchange (see Figure 40.8), or SPEKE. It was initially designed to avoid having to encrypt data using the password as the key, so as to avoid the problems that EKE suffers from. Instead, the password is used to derive the group's generator. The group G considered for SPEKE is the unique prime order subgroup of order q of the multiplicative group $\mathbb{Z}_p^*$, where again p is chosen to be a prime of the form $p = 2q + 1$. We assume that passwords can easily be viewed as elements in $\mathbb{Z}_p^*$. The protocol runs as follows:

- $\mathcal{A}$ first chooses $x \in \mathbb{Z}_q$ randomly and computes $X := pw^{2x}$. She sends X to $\mathcal{B}$;
- Upon receiving X, $\mathcal{B}$ chooses $y \in \mathbb{Z}_q$ randomly, computes $Y := pw^{2y}$, and sends back Y. He computes the key $X^{2y} = pw^{4xy}$;
- Finally, $\mathcal{A}$ computes the key $Y^{2x} = pw^{4xy}$.

In each of the flows and in the final key computation, the squaring operation is necessary to make sure the resulting element of $\mathbb{Z}_p^*$ is actually in G. (This prevents so-called *subgroup confinement attacks*; see [15].)

Security and Efficiency

Security and Efficiency by Design

Offline dictionary attack resistance in SPEKE is basically due to the fact that pw^2 generates G. This implies that pw^{2x} and pw^{2y} are random, independent elements in G, so they leak no information on pw. In case the key pw^{4xy} is leaked to the adversary as well, there does not seem to be any way to compute the password other than by first computing the discrete logarithm of the key to the base, say pw^{2x}, and then computing pw from pw^{2y}. Since DLP is presumed hard in G, this is infeasible. Finally, forward secrecy is basically ensured through the DDH assumption, which holds in G. (We mention here that it does not hold in the whole of $\mathbb{Z}_p^*$, however.)

$\mathcal{A}$		$\mathcal{B}$
x		y
$X := pw^{2x}$		$Y := pw^{2y}$
	$\xrightarrow{X}$	
	$\xleftarrow{Y}$	
$K_{\mathcal{A}} := Y^{2x}$		$K_{\mathcal{B}} := X^{2y}$

FIGURE 40.8 Simple password exponential key exchange.

The protocol is clearly very efficient, as it essentially consists of a Diffie-Hellman Key Exchange. As with EKE, the prime p has to be at least 1024 bits in length, so as to be sure the computing discrete logarithms will be difficult. Thus, also as in EKE, the random numbers chosen by the parties are quite large: at least 1023 bits in this case.

Security in Theory

Similarly to EKE, SPEKE's security has been theoretically studied. Namely, a proof of security for it can be found in [16]. However, without getting into the specific details, the result only guarantees that a *constant* number of passwords may be tested per online impersonation attempt, rather than at most one. Also, the model assumes idealized hash functions, similarly to the use of idealized encryption to analyze SPEKE. Finally, it is interesting to note that the formal proof of security rests on a rather rarely seen computational hardness assumption: the *decision additive-inverted Diffie-Hellman problem*. We refer to [16] for details.

Flaws

It has been shown in [17] that is possible to test many more than one password per impersonation attempt. For this to occur, the adversary first needs to find sets of passwords that are *exponentially equivalent*.

A set of passwords $\{pw_i\}$ is said to form an *exponential equivalence class* if there exists some integer a and a set of integers $\{j_i\}$ such that for all i we have $pw_i = a^{j_i}$. Since the password space is a small subset of $\mathbb{Z}_p^*$, an adversary can potentially find many such classes efficiently simply by computing successive sets of integers of the form a^j for various values of a and j. The point is, by impersonating one party and sending the single value a^r for any integer r, one protocol execution allows the adversary to test all of the passwords in the set $\{pw_i\}$. The details on this attack can be found in [17].

Now, testing implies that the adversary is able to verify its guess against the values it receives from the honest party. This is not strictly possible in the protocol described above; however, we already explained that PAKE protocols need key confirmation to achieve mutual authentication. Adding the key confirmation mechanism is what lets the adversary verify its guess, completing the attack.

We emphasize that this is not an argument against key confirmation, which is important for PAKE, but rather a reminder that in assessing a protocol's security correctly, all flows and the interactions between them should be considered simultaneously.

Proposed Standardization

A fully constrained SPEKE requires the parties to share knowledge of a large prime p of the form $p = 2q + 1$

where q is also prime. They also share the description of two distinct cryptographic hash function H_1 and H_2. The protocol runs as follows:

- $\mathcal{A}$ chooses $x \in \mathbb{Z}_q$ randomly and computes $X := H_1(pw)^{2x}$. She sends X to $\mathcal{B}$;
- Upon receiving X, $\mathcal{B}$ chooses $y \in \mathbb{Z}_q$ randomly, computes $Y := H_1(pw)^{2y}$ and X^{2y}. If this last value is 1 or $p-1$, he aborts the protocol. Otherwise, he computes $K := H_2(X^{2y})$ and $h := H_2(H_2(K))$. He sends Y and h to $\mathcal{A}$, and the session key will be K;
- Upon receiving Y and h, $\mathcal{A}$ computes Y^{2x}. If this value is 1 or $p-1$, she aborts the protocol. Otherwise, she computes $K = H_2(Y^{2x})$, and checks to see if h is equal to $H_2(H_2(K))$. If not, she aborts the protocol. Otherwise, she computes $h' = H_2(K)$, and sends h' back to $\mathcal{B}$. She sets the session key to being K;
- Finally, upon receiving h', $\mathcal{B}$ checks to see if h' equals $H_2(K)$. If not, he aborts; otherwise, he sets the session key to K.

A slight variant of SPEKE has been proposed for IEEE 1363.2 standardization by its inventor [15]. It differs from the protocol presented earlier in two ways. First, a key confirmation mechanism has been added, using the hash function H_2. Second, rather than squaring the password in $\mathbb{Z}_p^*$, it is first hashed using H_1. The efficiency of the protocol remains essentially the same, as hashing is a cheap operation. The key confirmation mechanism used here is portrayed in Figure 40.9. We now discuss the use of the additional operations that are performed.

Checking that X^{2y} and Y^{2x} are different from 1 and $p-1$ ensures that the initial jointly computed value is not the group's neutral element. This is necessary to prevent *subgroup confinement attacks*, see [15] for details. It is interesting to observe what is accomplished by the hashing operations.

Key Confirmation and Mutual Authentication

In the second protocol step, $\mathcal{B}$ computes h as $H_2(H_2(K))$ and sends this data to $\mathcal{A}$. The properties of the hash function guarantee that only the holder of the correct key K could have computed this string. Thus, in verifying that the value h she receives equals $H_2(H_2(K))$ where K here is the value of the session key she computes at her end, $\mathcal{A}$ gains confirmation that all along she has been communicating to an entity that must have had the correct password, since it was able to compute the right key. Since by assumption only $\mathcal{B}$ should know the password, $\mathcal{A}$ can safely conclude that she is indeed talking to $\mathcal{B}$, and furthermore that he has computed the session key. By a similar reasoning with h', $\mathcal{B}$ receives confirmation that he is indeed talking to $\mathcal{A}$, and that $\mathcal{A}$ holds the key.

Note that the reason $H_2(H_2(K))$ is sent *before* $H_2(K)$ is that when sent in this order, neither value can be computed by an adversary in time to attempt any damage. If $H_2(K)$ were sent first, an adversary could compute $H_2(H_2(K))$ on her own and fool $\mathcal{B}$ into thinking $\mathcal{A}$ has the key, while she may actually have nothing.

Defending against Exponential Equivalence

The role of the function H_1 is to prevent the attack described earlier. Hashing the password before squaring it makes it more difficult for an adversary to exploit exponential equivalence. However, known hash functions are not designed to guarantee that applying them to different values leads to integers that are not exponentially equivalent. See [17] for more details on this.

Password-Authenticated Key Exchange by Juggling

The last protocol we discuss is the J-PAKE [18] protocol of Hao and Ryan, first proposed in 2008. This protocol can be instantiated with any prime order cyclic group G in which the DDH assumption holds. Let G be such a group, g be a generator of G, and denote the order of G by q. J-PAKE also requires a *Zero Knowledge Proof* (ZKP) protocol for proving knowledge of discrete logarithms. Before describing J-PAKE, we briefly explain the role of the ZKP.

Interlude: Proving Knowledge of Discrete Logarithms

A ZKP protocol is run between two entities, the *prover* $\mathcal{P}$ and the *verifier* $\mathcal{V}$. The purpose of the protocol is for $\mathcal{P}$ to convince $\mathcal{V}$ that a certain statement is true without revealing any more information on that statement. For this to be

$\mathcal{A}$		$\mathcal{B}$
	$\xleftarrow{h}$	$h := H_2(H_2(K))$
Verify $h := H_2(H_2(K))$		
$h' := H_2(K)$	$\xrightarrow{h'}$	
		Verify $h' := H_2(K)$

FIGURE 40.9 Key confirmation with double hashing.

of any use to $\mathcal{V}$, it should be infeasible for a cheating $\mathcal{P}$ to trick $\mathcal{V}$ into believing a false statement.

Concretely, in our case $\mathcal{P}$ and $\mathcal{V}$ each know the description of group G and generator g, $\mathcal{P}$ holds a secret value $x \in \mathbb{Z}_q$, and $\mathcal{V}$ holds the public value g^x. The ZKP should allow $\mathcal{P}$ to convince $\mathcal{V}$ that $\mathcal{P}$ truly knows x, without revealing any information about x to $\mathcal{V}$ beyond that already revealed by g^x. Also, if $\mathcal{P}$ does not know x, it should be unable to produce a statement that would convince $\mathcal{V}$ that it does.

We denote $ZKP(x, g)$ the output of the algorithm that computes a proof of knowledge of x to the base g. We will give an example of how to instantiate ZKP with Schnorr signatures further below. More on ZKPs can be found for instance in [19].

J-PAKE

Let pw be the password that $\mathcal{A}$ and $\mathcal{B}$ share. We assume that it can be viewed as an element of $\mathbb{Z}_q$ and that $pw \neq 0$ [18]. The key exchange protocol runs as follows (see Figure 40.10):

- $\mathcal{A}$ chooses x_1 and x_2 randomly in $\mathbb{Z}_q$, with $x_2 \neq 0$, and computes $X_1 := g^{x_1}$, $X_2 := g^{x_2}$, and proofs of knowledge $ZKP(x_1, g)$ and $ZKP(x_2, g)$. She sends $(X_1, X_2, ZKP(x_1, g), ZKP(x_2, g))$ to $\mathcal{B}$;
- Upon receiving the first message, $\mathcal{B}$ verifies the knowledge proofs. He then chooses x_3 and x_4 randomly in $\mathbb{Z}_q$, with $x_4 \neq 0$, and computes X_3, X_4, $ZKP(x_3, g)$, and $ZKP(x_4, g)$. The tuple $(X_3, X_4, ZKP(x_3, g), ZKP(x_4, g))$ is sent back to $\mathcal{A}$;
- $\mathcal{A}$ verifies the knowledge proofs. She then computes $X_{\mathcal{A}} := (X_1X_3X_4)^{x_2pw}$, a proof of knowledge $ZKP(x_2pw, X_1X_3X_4)$, and sends $(X_{\mathcal{A}}, ZKP(x_2pw, X_1X_3X_4))$ to $\mathcal{B}$;
- $\mathcal{B}$ once again verifies the new knowledge proof. He then similarly computes $X_{\mathcal{B}} := (X_3X_1X_2)^{x_4pw}$, $ZKP(x_4pw, X_3X_1X_2)$, and returns $(X_{\mathcal{B}}, ZKP(x_4pw, X_3X_1X_2))$ to $\mathcal{A}$. He finally computes key $K_{\mathcal{B}} := (X_{\mathcal{A}}(X_2)^{-x_4})^{x_4pw}$;
- Upon receiving $(X_{\mathcal{B}}, ZKP(x_4pw, X_3X_1X_2))$, $\mathcal{A}$ verifies the knowledge proof, and computes the key $K_{\mathcal{A}} := (X_{\mathcal{B}}(X_4)^{-x_2})^{x_2pw}$.

A careful examination of the group elements sent shows that $K_{\mathcal{A}} = K_{\mathcal{B}} = g^{(x_1+x_3)x_2x_4pw}$.

A Concrete ZKP Protocol

The authors of [18] suggest using Schnorr signatures [20] to prove knowledge of exponents to a given base. We review how this is done here. We keep the earlier notation that was shown; let H be a hash function. Suppose prover $\mathcal{P}$ wishes to prove knowledge of x such that $X = g^x$ to verifier $\mathcal{V}$. The prover does the following:

i. $\mathcal{P}$ selects v randomly from $\mathbb{Z}_q$;
ii. $\mathcal{P}$ sets $V := g^v$ and $h := H(\mathcal{P}, g, V, X)$;
iii. $\mathcal{P}$ sets $r := v - xh$;
iv. $\mathcal{P}$'s proof is (V, r).

To verify the proof, $\mathcal{V}$ first checks that V is a valid group element, that is, is of order q, and then checks that $V = g^rX^h$, where he recomputes h using H, his input (g, X, V), and $\mathcal{P}$'s identity.

The security of Schnorr signatures used as ZKPs is well known. Details on how this can be proven can be found in [1]. (See Schnorr's identification scheme.)

J-PAKE's Security

The offline dictionary attack resistance is essentially due to the fact that the DDH assumption holds in G. The transmitted group elements that depend on the password are $(X_1X_3X_4)^{x_2pw}$ and $(X_3X_1X_2)^{x_4pw}$, and even given the first four group elements sent, these values still look like random values; hence, the password is completely protected from eavesdropping adversaries. If the adversary is active, that is, posing for instance as $\mathcal{B}$, then the value $(X_1X_3X_4)^{x_2pw}$ it receives from $\mathcal{A}$ still looks like a random element again

$\mathcal{A}$		$\mathcal{B}$
(x_1, x_2)		(x_3, x_4)
	$\xrightarrow{(X_1, X_2, ZKP(x_1,g), ZKP(x_2,g))}$	
	$\xleftarrow{(X_3, X_4, ZKP(x_3,g), ZKP(x_4,g))}$	
$X_{\mathcal{A}} := (X_1X_3X_4)^{x_2pw}$		$X_{\mathcal{B}} := (X_3X_1X_2)^{x_4pw}$
	$\xrightarrow{(X_{\mathcal{A}}, ZKP(x_2pw, X_1X_3X_4))}$	
	$\xleftarrow{(X_{\mathcal{B}}, ZKP(x_4pw, X_3X_1X_2))}$	
$K_{\mathcal{A}} := (X_{\mathcal{B}}(X_4)^{-x_2})^{x_2pw}$		$K_{\mathcal{B}} := (X_{\mathcal{A}}(X_2)^{-x_4})^{x_4pw}$

FIGURE 40.10 J-PAKE protocol.

under the DDH assumption. This is because it contains a factor of the form $g^{x_1 x_2}$, where x_1 and x_2 are chosen randomly by the honest party $\mathcal{A}$. Now, one may think that the malicious $\mathcal{B}$ could try to cancel out or otherwise manipulate x_1 in this formula by computing X_3 as some function of X_1; but this is not possible by virtue of the fact that X_3 needs to be accompanied by a proof of knowledge of x_3.

One must also pay attention to the accompanying zero-knowledge proofs, since the last two proofs that are transmitted prove knowledge of exponents that are computed using the password. However, by design these proofs leak no more information about these exponents than what is already known.

Forward secrecy is also guaranteed by the DDH assumption essentially because even given the tuple

$$(q, G, g, g^{x_1}, g^{x_2}, g^{x_3}, g^{x_4}, g^{(x_1+x_3+x_4)x_2}, g^{(x_3+x_1+x_2)x_4})$$

the adversary cannot tell apart the value $g^{(x_1+x_3)x_2 x_4}$ from a random group element, much less compute it. Finally, known-session key security follows from the fact that fresh random values are chosen in each protocol run. Thus, session keys are all independent.

Flaws

As of yet, no flaws have been found in J-PAKE's security. On the other hand, the security rests in part on that of the ZKP protocol used. To be able to efficiently integrate such a tool into the protocol, it is necessary to make it noninteractive, and current state-of-the-art techniques can only provably achieve this in models that use idealized hash functions (this is known as the *random oracle* model). In particular, Schnorr's signature scheme is proven secure using an idealized hash function. This observation has not yet led to any practical attacks on J-PAKE, but one must remain cautious.

It can be argued that the protocol may not be very practical given the number of sent messages and exponentiations needed, especially taking into account the additional computations that are necessary to prove knowledge of discrete logarithms. However, in comparing J-PAKE with EKE and SPEKE, one must also bear in mind the underlying groups that are involved. J-PAKE can work in groups with special structure provided the DDH assumption holds. For instance, G can be the multiplicative subgroup of order q of the group $\mathbb{Z}_p^*$ where p is a prime of the form $p = rq + 1$ for r coprime to q and q prime, and $r > 2$. The length of q can thus be around 160 bits rather than 1024. This makes selecting random elements in $\mathbb{Z}_q$ much more efficient. Other groups that can be used to increase efficiency are elliptic curve groups. The reader can find a good presentation of the DDH assumption and examples of families of groups that are believed to verify it in [21].

Proposed Standardization

J-PAKE has also been submitted as a potential candidate for IEEE standardization. In [18], the inventors of the protocol suggest either of the methods employed for EKE and SPEKE to achieve key confirmation. Taking into account this added exchange, the protocol remains secure.

Patents and Deployment

Both EKE and an augmented version of EKE have been patented by Lucent Technologies, now Alcatel-Lucent (U. S. patent 5,241,599 [22] and U.S. patent 5,440,635 [23], respectively). The former expired in 2011, and the latter will expire in 2013. SPEKE is also covered by U.S Patent 6,226,383 [24], which is owned by Phoenix technologies. It is due to expire in 2017 [24].

The patent issue has been a brake to deployment of PAKEs. For instance, at the beginning of 2012 there were no publicly known implementations of EKE according to the Gèant project (see the DJ3.1.2,1 document on roaming developments in the Gèant deliverables link on **www.geant.net**). There have been, however, IETF information notes on integrating EKE to the EAP (see checklist; An Agenda for Action for Implementing Procedures for Extensible Authentication Protocol (EAR) Methods) authentication framework. (RFC 6124, which can be found at **http://tools.ietf.org/html/rfc6124**, seems to be the latest.)

SPEKE on the other hand seems easier to locate. It is used in BlackBerry devices (produced by Research in Motion), for instance, in the Enterprise Server or Playbook Tablet. (The reader can search for SPEKE in the general knowledge base of BlackBerry's Website: **http://btsc.webapps.blackberry.com/btsc/microsites/microsite.do**.) It is also used in Entrust's TruePass end-to-end Web security product. (See the Entrust TruePass Technical Portfolio Overview document in the list of white papers of Entrust's Website: **http://www.entrust.com/resources/whitepapers.cfm**.) Funk Software—now Juniper Networks—and Interlink Networks have also used SPEKE for RADIUS systems in the past, although Interlink has discontinued SPEKE in its RAD-series product line starting version 7.1 or higher. (See the release notes in the documentation provided on their Website: **http://www.interlinknetworks.com/aaa_documentation.htm#notes**), and SPEKE no longer appears in Juniper's online glossary, suggesting that it may have stopped using the algorithm as well. (See **http://www.juniper.net/techpubs/en_US/release-**

An Agenda for Action for Implementing Procedures for Extensible Authentication Protocol (EAP) Methods

Every EAP method consists of several procedures that are necessary to ensure the security goals, enable crypto-agility and backward compatibility, and prevent attacks. These procedures can be executed sequentially, in parallel or in an interleaved fashion. For example, authentication and key establishment could be combined into an authenticated key establishment process. If the authentication or key establishment algorithm is not negotiated as part of the ciphersuite negotiation, both the ciphersuite negotiation and the algorithm can be started at the same time. The EAP methods under consideration may include the following procedures (check all tasks completed):

_____**1.** Ciphersuite negotiation to enable crypto-agility and backward compatibility.

_____**2.** Mutual authentication of a peer and the EAP server to ensure that federal peers and federal EAP servers provide assurance of their acclaimed identities to each other.

_____**3.** Key establishment between a peer and the EAP server to provide keying material to protect the remainder of the EAP execution and the wireless link.

_____**4.** Service information exchange to ensure the detection of malicious information sent by rogue authenticators or other rogue intermediary entities.

_____**5.** Message protection to utilize the established keying material to protect the remainder of the EAP execution.

independent/glossary/index.html, last checked August 30, 2012.)

As for J-PAKE, it is in the public domain and is used by Mozilla in Firefox Sync. (See the "How Firefox does it" paragraph in the Mozilla Services Sync Client documentation at: http://docs.services.mozilla.com/sync/lifeofasync.html.)

4. SUMMARY

In this chapter, we have given a short overview on a specific variant of authenticated key exchange protocols: that in which authentication between parties is established through knowledge of a simple, human-memorable password. Since passwords are overwhelmingly present in today's digital world, the study and development of these methods is important.

The most notable aspect of security introduced by this concept is defending against dictionary attacks, in which online or offline attackers attempt to test password guesses against transcripts of protocol executions. Recall that passwords are vulnerable to this precisely because of the low entropy they suffer from in order to achieve user-friendliness.

We have also presented three such protocols—namely, EKE, SPEKE, and J-PAKE—and discussed their security properties. Research in this area is still quite active; many other protocols besides those described here have been proposed and analyzed from both practical and theoretical standpoints. We refer to [12], [13], and [18] for more extensive bibliographies.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? A fresh key is established for each new conversation in which the parties may want to engage; such conversations are called sessions, and the keys used to secure them are called session keys.
2. True or False? A huge amount of key exchange protocols still use the Diffie-Hellman construct as a basis for computing secret keys.
3. True or False? There are essentially two flavors of authentication that can be used within a key exchange protocol.
4. True or False? In what is considered classical key exchange, the long-term keying material that a user is required to possess is usually one of two kinds: (i) a cryptographically secure key for a symmetric cryptographic algorithm (a 128-bit AES encryption key; see Chapter 37) or (ii) a cryptographically secure public key/secret key pair for an asymmetric cryptographic algorithm.
5. True or False? Another type of established long-term keying material that can be used is certified public key/secret key pairs.

Multiple Choice

1. Another method that has been considered to authenticate users involves using human
   A. passwords
   B. PAKE
   C. cryptography
   D. biometrics
   E. key exchange

2. Passwords are low-entropy data. This makes them vulnerable to ____________, which are essentially brute-force guessing attacks
   A. security attacks
   B. key exchanges
   C. dictionary attacks
   D. protocol attacks
   E. PAKE attacks

3. What are active attacks in which the adversary tries to guess the password through successive login attempts: The adversary engages over and over in the protocol, trying out different passwords, and when the opposing party stops aborting, the adversary knows it guessed the right password?
   A. Evolution attacks
   B. Residue class attacks
   C. Online dictionary attacks
   D. Certification authority attacks
   E. Security attacks

4. A user's password in a _____________ is viewed as a long-term key (it is expected to be used many times to create random, independent session keys).
   A. session key
   B. PAKE protocol
   C. known-session key security
   D. forward secrecy
   E. security protocol

5. Resistance to __________ (in which an adversary who compromised a user's long term key can then impersonate other parties to that user), is not satisfied by a PAKE: the other holder of the password can always be impersonated to the attacked user.
   A. physical world
   B. data retention
   C. standardization
   D. key compromise impersonation
   E. signature

EXERCISE

Problem

A PAKE protocol transcript cannot be allowed to leak a single bit of information on the password. Please explain further.

Hands-On Projects

Project

The security of EKE's main protocol flows has been studied from a purely theoretical point of view. Please explain and expand on this topic further.

Case Projects

Problem

The protocol is clearly very efficient, as it essentially consists of a Diffie-Hellman Key Exchange. Please explain and expand on this topic further.

Optional Team Case Project

Problem

A ZKP protocol is run between two entities, the prover P and the verifier V. Please explain further.

Chapter 41

Instant-Messaging Security

Samuel J.J. Curry
RSA

Instant messaging (IM) has been through several phases in the technology roller-coaster from exciting, cutting edge technology used by the socially avant-garde to a solid tool in the productivity toolkit of the most conservative organization. You would have to practically live under a rock (or at least not own a computer, personal digital assistant [PDA], or cell phone) to not have used it, much less to not know what it is. Luddites[1] notwithstanding, most people who use IM and even many people in information technology (IT) do not know how it works, why it is here, and what it means. In many deployments, IM can be a valuable contributor to business infrastructure, but it shouldn't be adopted without due consideration of business value (that is, is this worth doing?), business risk (that is, what is at stake?), and the people, processes, and technologies that will make it valuable and secure. This chapter should help you make a plan, keep it current, and make sure that it makes a difference.

1. WHY SHOULD I CARE ABOUT INSTANT MESSAGING?

When considering IM, it is important to realize that it is first and foremost a technology; it is not a goal in and of itself. Like an ERP[2] system, an email system, a database, a directory, or a provisioning system, IM must ultimately serve the business: it is a means to an end. The end should be measured in terms of *quantifiable* returns and should be put in context. Before engaging in an IM project, you should be clear about why you are doing it. The basic reasons you should consider IM are:

- Employee satisfaction
- Improving efficiency
- Performing transactions (some business transactions have been built, as you'll see later, to use IM infrastructures; those who do this are aware of it and those who have not seen it before are frequently horrified)
- Improving communications
- Improving response times and timelines

Business decisions revolve around the principle of acceptable risk for acceptable return, and as a result, your *security* decisions with respect to IM are effectively *business* decisions. To those of you reading this with a security hat on, you've probably experienced the continued rapprochement of security and business in your place of work (and in some cases the splitting of security into both a technical and a business discipline): IM is no exception to that. So let's look at IM, trends, the business around it, and then the security implications.

2. WHAT IS INSTANT MESSAGING?

IM is a technology in a continuum of advances (q.v.) that have arisen for communicating and collaborating over the Internet. The most important characteristic of IM is that it has the appearance of being in "real time," and for all intents and purposes it is in real time.[3] Of course, some IM systems allow for synchronization with folks who are offline and come online later through buffering and batching delivery, although these aren't really "instant" messaging (ironically, this is coming back with the advent of some features in social networking applications and environments like Facebook).

IM technologies predate the Internet, with many early mainframe systems and bulletin board systems (BBS) having early chat-like functionality, where two or more

1. Luddites were a British social movement in the textile industry who protested against the technological changes of the Industrial Revolution in the 19th century (http://en.wikipedia.org/wiki/Luddites).
2. Enterprise resource planning is a category of software that ties together operations, finance, staffing, and accounting. Common examples include SAP and Oracle software.

3. The debate over what constitutes real time is a favorite in many technical circles and is materially important when dealing with events and their observation in systems in which volumes are high and distances and timing are significant. When dealing with human beings and the relatively simple instances of whom we interact with and our perceptions of communications, it is far simpler to call this "real time" than "near real time."

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00041-6

people could have a continuous dialogue. In the post-mainframe world, when systems became more distributed and autonomous, chatting and early IM technologies came along, too. In the world of the Internet, two basic technologies have evolved: communications via a central server and communications directly between two peers. Many IM solutions involve a hybrid of these two basic technologies, maintaining a directory or registry of users that then enable a peer-to-peer (P2P) connection.

Some salient features that are relevant for the purposes of technology and will be important later in our approaches to securing instant messaging are as follows:

- *Simultaneity.* IM is a real time or "synchronous" form of communication—real-time opportunity and real-time risk.
- *Recording.* IM transactions are a form of written communication, which means that there are logs and sessions can be captured. This is directly analogous to email, although it can be hard to instrument in a P2P connection.
- *Nonrepudiation.* Instant messaging usually involves a dialogue and the appearance of nonrepudiation by virtue of an exchange, but there is no inherent nonrepudiation in most IM infrastructures. For example, talking to "Bobby" via IM does not in any way prove that it is registered to "Bobby" or is actually "Bobby" at the time you are talking to the other user.
- *Lack of confidentiality and integrity.* There is no guarantee that sessions are private or unaltered in most IM infrastructures without the implementation of effective encryption solutions.
- *Availability.* Most companies do not have guaranteed service-level agreements around availability and yet they depend on IM, either consciously or unknowingly and suffer the costs of supporting the service when it fails.

Most users of an IM infrastructure also treat IM as an informal form of communication. It's also not subject to the normal rules of behavior, formatting, and formality of other forms of business communication, such as letters, memoranda, and email.

3. THE EVOLUTION OF NETWORKING TECHNOLOGIES

Over time, technology changes and, usually, advances. Advancements in this context generally refer to being able to do more transactions with more people for more profit. Of course, generalizations of this sort tend to be true on the macroscopic level only since at the microscopic level the tiny deltas in capabilities, offerings, and the vagaries of markets drive many small changes, some of which are detrimental. However, over the long term and at the macroscopic level, advances in technology enable us to do more things with more people more easily and in closer to real time.

There are more than a few laws that track the evolution of some distinct technology trends and the positive effects that are expected. A good example of this is Moore's Law, which has yet to be disproven and has proven true since the 1960s. Moore's Law, put simply, postulates that the number of transistors that can be effectively integrated doubles roughly every two years, and the resultant computing power or efficiency increases along with that. Most of us in technology know Moore's Law, and it is arguable that we as a society depend on it for economic growth and stimulus: There is always more demand for more computing power (or has been to date and for the foreseeable future). A less known further example is Gilder's Law[4] (which has since been disproven) that asserts that a similar, related growth in available bandwidth occurs over time.

Perhaps the most important "law" with respect to networks and for instant messaging is Metcalfe's Law, which states that the value of a telecommunications network increases exponentially with a linear increase in the number of users. (Actually, it states that it is proportional to the square of the users on the network.)

Let's also assume that over time the value of a network will increase; the people who use it will find new ways to get more value out of it. The number of connections or transactions will increase, and the value and importance of that network will go up. In a sense, it takes time once a network has increased in size for the complexity and number of transactions promised by Metcalfe's Law to be realized. What does all this have to do with IM? Let's tie it together:

- Following from Moore's Law (and to a lesser extent Gilder), computers (and their networks) will get faster and therefore more valuable—and so connecting them in near real time (of which IM is an example of real-time communications) is a *natural occurrence* and will *increase value.*
- Following from Metcalfe, over time networks will become increasingly valuable to users of those networks.

In other words, IM as a phenomenon is really a tool for increasing connections among systems and networks and for getting more value. For those of us in the business world, this is good news: using IM, we should be able to realize more value from that large IT investment and should be able to do more business with more people more efficiently. That is the "carrot," but there is a stick,

4. www.netlingo.com/lookup.cfm?term=Gilder's%20Law.

too: It is not all good news, because where there is value and opportunity, there is also threat and risk.

4. GAME THEORY AND INSTANT MESSAGING

Whenever gains or losses can be quantified for a given population, game theory applies. Game theory is used in many fields to predict what is basically the *social* behavior or organisms in a system: people in economics and political science, animals in biology and ecology, and so on. When you can tell *how much* someone stands to gain or lose, you can build reasonably accurate predictive models for how they will behave; and this is in fact the foundation for many of our modern economic theories. The fact of the matter is that now that the Internet is used for business, we can apply game theory to human behavior with Internet technologies, too, and this includes IM.

On the positive side, if you are seeing more of your colleagues, employees, and friends adopt a technology, especially in a business context, you can be reasonably sure that there is some gain and loss equation that points to an increase in value behind the technology. Generally, people should not go out of their way to adopt technologies simply for the sake of adopting them on a wide scale (though actually, many people do just this and then suffer for it; technology adoption on a wide scale and over a long period of time generally means that something is showing a return on value). Unfortunately, in a business context, this may not translate into more business or more value for the business. Human beings not only do things for quantifiable, money-driven reasons; they also do things for moral and social reasons.

Let's explore the benefits of adopting IM technology within a company, and then we can explore the risks a little more deeply.

Your Workforce

Whether you work in an IT department or run a small company, your employees have things they need to do: process orders, work with peers, manage teams, talk to customers and to partners. ΓM is a tool they can and will use to do these things. Look at your workforce and their high-level roles: Do they need ΓM to do their jobs? ΓM is an entitlement within a company, not a right. The management of entitlements is a difficult undertaking, but it isn't without precedent. For older companies, you probably had to make a decision similar to the IM decision with respect to email or Internet access. The first response from a company is usually binary: Allow everyone or disallow everyone. This reactionary response is natural, and in many cases some roles are denied entitlements such as email or Internet access on a regular basis. Keep in mind that in some industries, employees make the difference between a successful, aggressively growing business and one that is effectively in a "maintenance mode" or, worse, is actively shrinking. In the remainder of this chapter, we outline factors in your decision making, as follows with the first factor.

Factor #1

Do your employees need IM? If so, which employees need IM and what do they need it for?

Examples of privileged IM entitlement include allowing developers, brokers, sales teams, executives, operations, and/or customer support to have access. *Warning:* If you provide ΓM for some parts of your company and not for others, you will be in a situation in which some employees have a privilege that others do not. This will have two, perhaps unintended, consequences:

- Employees without IM will seek to get it by abusing backdoors or processes to get this entitlement.
- Some employees will naturally be separated from other employees and may become the object of envy or of resentment. This could cause problems.

We have also touched on employee satisfaction, and it is important to understand the demographics of your workplace and its social norms. It is important to also consider physical location of employees and general demographic considerations with respect to IM because there could be cultural barriers, linguistic barriers, and, as we will see later, generational ones, too.

Factor #2

Is IM important as a job satisfaction component?

Economists generally hold that employees work for financial, moral, and social reasons. Financial reasons are the most obvious and, as we've seen, are the ones most easily quantified and therefore subject to game theory; companies have money, and they can use it to incent the behaviors they want. However, we as human beings also work on things for moral reasons, as is the case with people working in nonprofit organizations or in the open-source movement. These people work on things that matter to them for moral reasons.

However, the social incentives are perhaps the most important for job satisfaction. In speaking recently with the CIO of a large company that banned the use of external IM, the CIO was shocked that a large number of talented operations and development people refused lucrative offers on the grounds that IM was disallowed with people outside the company. This led to a discussion of the motivators for an important asset for this

company: attracting and keeping the right talent. The lesson is that if you want to attract the best, you may have to allow them to use technologies such as IM.

After you have determined whether or not IM is needed for the job (Factor #1), interview employees on the uses of IM in a social context: with whom do they IM and for what purposes? Social incentives include a large number of social factors, including keeping in touch with parents, siblings, spouses, and friends but also with colleagues overseas, with mentors, and for team collaboration, especially over long distances.

Generational Gaps

An interesting phenomenon is observable in the generation now in schools and training for the future: They multitask frequently. Generational gaps and their attendant conflicts are nothing new; older generations are in power and are seen to bear larger burdens, and younger generations are often perceived in a negative light. Today IM may be at the forefront of yet another generational conflict.

If you've observed children recently, they do more all at once than adults have done in the past 20 years. This is a generation that grows up in a home with multiple televisions, multiple computers, cell phones from a young age, PowerPoint in the classroom, text messaging, email,[5] and IM.

The typical older-generation values in a generational conflict that we must watch out for are assuming that the younger generation is inherently more lazy, is looking for unreasonable entitlement, wants instant gratification, or is lacking in intelligence and seasoning. If you catch yourself doing this, stop yourself and try to empathize with the younger folks. Likewise, the younger generation has its pitfalls and assumptions; but let's focus on the younger, emerging generation, because they will soon be entering the workforce. If you find yourself assuming that multitasking and responding to multiple concurrent stimuli is distracting and likely to produce a lack of efficiency, stop and run through a basic question: Is what's true for you immediately true for the people you are interacting with? This leads to Factors 3 and 4.

Factor #3

Does IM improve or lessen efficiency?

With respect to IM, does I'M (and the interruptions it creates) have to mean that someone is less efficient, or could they be more efficient because of it? As we've seen, it is possible that many younger employees can have multiple IM conversations and can potentially get a lot more done in less time compared to either sending out multiple emails or waiting for responses. In many respects, this question is similar to the questions that the BlackBerry raised when it was introduced to the workforce, and there are three ways that it can be answered:

- In some cases, jobs require isolation and focus, and a culture of IM can create conditions that are less effective.
- In some cases, it doesn't matter.
- In some cases, some employees may be much more effective when they receive maximum stimulus and input.

Factor #4

Will this efficiency change over time, or is it in fact different for different demographics of my workforce?

Consider generational differences and the evolution of your workforce. This may all be moot, or there may be a *de facto* acceptance of IM over time, much as there was with email and other, older technologies in companies. It is interesting to note that younger, newer companies never consider the important factors with respect to IM because *they culturally assume it is a right.* This assumption may form the basis of some real conflicts in the years to come. Imagine companies that shut off new technologies being sued over "cruel and unusual" work conditions because they are removing what employees assume to be a right. Of course, this conflict is small now, but it is important to have a process for dealing with new technologies within the corporation rather than being blindsided by them as they emerge or, worse, as a new generation of users find themselves cut off from stimuli and tools that they consider necessary for their job or for their quality of life. In the end, the first four factors should help you define the following three items:

- Do you need IM as a company?
- Why do employees need it?
  - To do their jobs?
  - To improve efficiency?
  - To do more business?
  - To work with peers?
  - To improve employee satisfaction?
- Who needs it?

Without answers to these questions, which are all about the workforce as a whole, the role of IM will not be easily understood nor established within the company.

5. To my amusement, my goddaughter, who is 11, recently told me that "email was old fashioned" and she couldn't believe that I used it so heavily for work!

Transactions

Some companies have taken a bold step and use IM infrastructure for actual business processes. These are typically younger, fast-growing companies that are looking for more real-time transactions or processes. They typically accept a higher level of risk in general in exchange for greater potential returns. The unfortunate companies are the ones that have built product systems and processes on an IM infrastructure *unknowingly* and now have to deal with potentially unintended consequences of that infrastructure.

How does this happen? The infrastructures for IM on the Internet are large, ubiquitous, and fairly reliable, and it is natural that such infrastructures will get used. As we saw in the section on the evolution of Internet technologies, users will find ways to increase complexity and the value of networks over time, in essence fulfilling Metcalfe's Law. This is why some companies find that a small team using I'M (where a built in business process on an IM application has grown fast, with real-time response times for some processes) has now reached the point where sizeable business and transactions are conducted over IM.

Factor #5

Does your company have a need or dependency on IM to do business?

If this is the case, you need to understand immediately which applications and infrastructures you rely on. You should begin a process for examining the infrastructure and mapping out the business processes:

- Where are the single points of failure?
- Where does liability lie?
- What is availability like?
- What is the impact of downtime on the business?
- What is the business risk?
- What are your disaster recovery and business continuity options?

The answers to these questions will lead to natural action plans. They will also follow the basic rule of acceptable risk for acceptable return, unless you find you have a regulatory implication (in which case, build action plans immediately).

Factor #6

Are you considering deploying a technology or process on an IM infrastructure?

If this is the case, you need to understand immediately which applications and infrastructures you will rely on. You should begin a process for understanding the infrastructure and quantifying and managing the business risk. Again, make sure, as with the workforce, that you in fact need the IM infrastructure in the first place.

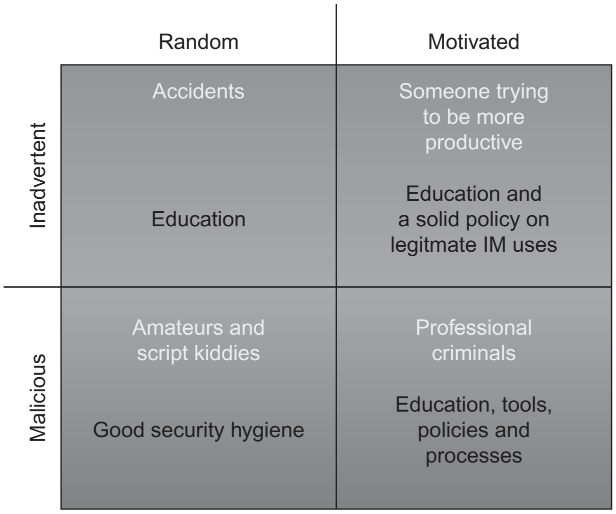

FIGURE 41.1 Populations that present a corporate risk and the correct responses to each.

5. THE NATURE OF THE THREAT

There are some clear threats, internal and external, and both inadvertent and malicious. These different threats call for the implementation of different countermeasures. Figure 41.1 shows a simple grid of the populations that a security professional will have to consider in the context of their security postures for IM.

Malicious Threat

We've looked at the good guys, who are basically looking within the company or are perhaps partners looking to use a powerful, real-time technology for positive reasons: more business with more people more efficiently. Now it is time to look at the bad guys: black hats.[6]

In the "old days," black hats were seen to be young kids in their parents' basements, or perhaps a disgruntled techie with an axe to grind. These were people who would invest a disproportionate amount of time in an activity, spending hundreds of hours to gain fame or notoriety or to enact revenge. This behavior led to the "worm of the week" and macro-viruses. They were, in effect, not a systematic threat but were rather background noise. We

6. This term was a difficult one to choose. I opted not to go with *crackers* or *hackers* but rather with *black hats* because that is the most neutral term to refer to malicious computer exploiters.

will calls these folks "amateurs" for reasons that will become clear.

There have also always been dedicated black hats, or "professionals," who plied their trade for gain or as mercenaries. These folks were at first in the minority and generally hid well among the amateurs. In fact, they had a vested interest in seeing the proliferation of "script kiddies" who could "hack" easily: This activity created background noise against which their actions would go unnoticed. Think of the flow of information and activity, of security incidents as a CSI scene where a smart criminal has visited barber shops, collected discarded hair from the floors, and then liberally spread them around the crime scene to throw off the DNA collection of forensic investigators. This is what the old-world professionals did and why they rejoiced at the "worms of the week" that provided a constant background noise for them to hide their serious thefts.

Now we come to the modern age, and the professionals are in the majority. The amateurs have grown up and found that they can leave their parents' basements and go out and make money working for real organizations and companies, plying their skills to abuse the Internet and systems for real gain. This is what led to the proliferation of Spyware; and because it is an *economic* activity, we can quantify losses and gains for this population and can begin to apply game theory to predicting their behaviors and *the technologies that they will abuse for gain.*

There is a new category as well around the *Advanced Persistent Threat* or APT.[7] These attackers are likewise professionals and highly motivated by a mission. They are also well funded and include both nation states and hacktivists looking for key intelligence and access: economic, military or political access, information and control.

On the one hand, the bad guys are now a vested interest, as has been well documented[8] and analyzed; they are a sustained, real, commercial interest and present a clear and present risk to most IT infrastructures. On the other hand, there are well-funded APTs that are specifically determined to break in and achieve their mission, which you are empowered and responsible for stopping. Keep in mind the following general rules about these online miscreants:

- It is not about ego or a particular trick; they are not above using or abusing any technology.
- They do what they do to make money or to achieve their mission. This is your money, your IP and your trust they are threatening. They are a risk to you and to your company.
- They are sophisticated; they have supply and distribution agreements and partners, they have SLAs[9] and business relationships, they have allies and enemies, and they even have quality labs, alliances and conferences. They are not merely immature adults or precocious adolescents.

In general, online criminals will seek to exploit IM if they can realize value in the target and if they can efficiently go after it. IM represents a technology against which it is easy for black hats to develop exploits, and even relatively small returns (such as a 1% click rate on SPIM, which stands for *spam instant messaging*) would have enormous potential value.

Factor #7

Does the value to the company of information and processes carried over IM represent something that is a valuable target (because it can either affect your business or realize a gain)? Do you have have information or processes that are valuable to your customers or partners? This should include the ability to blackmail employees and partners: Can someone learn things about key employees that they could use to threaten or abuse employees and partners?

The answer to this question will help put in perspective the potential for IM technology to be abused.

Factor #8

If the IM technology were abused or compromised, what would be the risk to the business or to a customer or partner?

SPIM, worms, viruses, spyware, Trojans, rootkits, backdoors and other threats can spread over IM as readily as email, file shares, and other transmission vectors—in fact, it is arguable that it can spread more readily via IM. Will an incident over IM cause an unacceptable risk to the business? This should be answered in the same way as "Will an incident over email cause an unacceptable risk to the business?" For most organizations the answer should always be yes.

Vulnerabilities

Like any form of software (or hardware), IM applications and infrastructure are subject to vulnerabilities and weaknesses from poor configuration and implementation. Most of these applications do not have the same degree of rigor

7. I prefer Josh Corman's term of *Advanced Persistent Adversary* since this most accurately reflects the Human nature of this class of threat. However, I will use APT as the more common term of the day.
8. www.rsa.com/blog/blog. aspx#Security-Blog.

9. Service-level agreement.

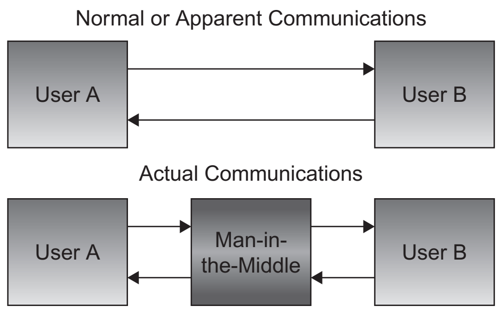

FIGURE 41.2 Normal versus man-in-the-middle communications.

around maintenance, support, and patching as other enterprise software applications. As a result, it is important to have processes for penetration testing and security audits and to establish a relationship, if possible, with manufacturers and distributors for enterprise caliber support. In many cases, the total cost of ownership of an IM infrastructure and applications may rise considerably to make up for this lack. For this reason, using the freeware services may be a temptation, but the risks may quickly outweigh the savings.

Man-in-the-Middle Attacks

A man-in-the-middle attack is a class of attack in which a third party acts as a legitimate or even invisible broker. As shown in Figure 41.2, an attacker is posing to each user in an IM transaction as a legitimate part of the process while in fact recording or relaying information. This is a common attack philosophy, and without basic mutual authentication or encryption tools, it is inexpensive for black hats to carry out in a wide-scale manner.

As a security professional, it is possible to monitor IM protocols and the IP addresses with which they communicate, allowing IM to and from only certain recognized hubs. Even this is not perfect, because "X-in-the-middle" attacks in their most generic form can include everything from Trojans and keyloggers to line taps. It is also possible to monitor communications among peers, although effectively looking for man-in-the-middle attacks in this way is difficult.

Phishing and Social Engineering

Social engineering is the practice of fooling someone into giving up something they wouldn't otherwise surrender through the use of psychological tricks. Social engineers rely on the normal behavior of people presented with data or a social situation to respond in a predictable, human way. An attack of this sort will rely on presenting trusted logos and a context that seems normal but is in fact designed to create a vulnerability that the social engineer can exploit. This is relevant to IM because people can choose IM identities *similar to ones with whom the user normally communicates.* The simplest attack of all is to get an identity that is similar to a boss, sibling, friend, or spouse and then provide information to get information. Employees should be educated to always directly check with end users to ensure that they are in fact communicating with whom they believe they are communicating.

Knowledge is the Commodity

It goes without saying that knowledge of business transactions is itself something that can be turned to profit. The contents of a formula, the nature of an experiment, the value and type of a financial transaction are all important to competitors and to speculators. Stock values rise and fall on rumors of activity, and material knowledge of what is happening can be directly translated into profit.

There are companies, organizations, and individuals that launder money and reap huge profits on the basis of insider information and intellectual property, and the bad guys are looking for exactly this information. Know what is being communicated and educate your employees about the open, real-time, and exposed nature of IM. Make sure that you have solid policies on what is acceptable to communicate over IM.

Factor #9

What intellectual property, material information, corporate documents, and transaction data are at risk over IM?

Make sure that you know what people use IM for and, if you do not have the means to control it, consider denying access to IM or implementing content-filtering technologies. With false positives and technology failing to track context of communications, do not rely heavily on a technological answer; make sure you have educational options and that you document use of IM in your environment.

Data and Traffic Analysis

The mere presence of communications is enough, in some circumstances, to indicate material facts about a business or initiative. This is particularly well understood by national governments and interests with "signals intelligence." You do not have to know what someone is saying to have an edge. This has been seen throughout history, with the most obvious and numerous examples during World War II: If you know that someone is communicating, that is in effect intelligence.

Communicating with a lawyer, making a trade, and the synchronizing in real time of that information with public data may construe a material breach if it's intercepted. Wherever possible, artificial traffic levels and data content

flags to the outside world should be used to disguise the nature and times of communication for transactions that indicate insider information or transactions that you otherwise wouldn't want the world to know about.

Factor #10

What do transaction types and times tell people about your business? Is it acceptable for people to have access to this information?

Some of the most important events in history have occurred because of intelligence not of what was said but rather how, and most important why, a communication occurred.

Unintentional Threats

Perhaps the most insidious threat isn't the malicious one; it is the inadvertent one. Employees are generally seeking to do more work more efficiently. This is what leads to them using their public, Web-based emails for working at home rather than only working in the office. Very often people who are working diligently do something to try to work faster, better, or in more places and they inadvertently cause a business risk. These are, in effect, human behaviors that put the company at risk, and the answer is both an educational one and one that can benefit from the use of certain tools.

Intellectual Property Leakage

Just as employees shouldn't leave laptops in cars or work on sensitive documents in public places such as an airport or coffee shop, they also should not use public IM for sensitive material. Intellectual property leakage of source code, insider information, trade secrets, and so on are major risks with IM when used incorrectly, although it should be noted that when deployed correctly, such transactions can be done safely over IM (when encrypted and appropriate, with the right mutual authentication).

Inappropriate Use

As with Web browsing and email, inappropriate use of IM can lead to risks and threats to a business. In particular, IM is an informal medium. People have their own lingo in IM, with acronyms[10] peculiar to the medium (B4N = bye for now, HAND = have a nice day, IRL = in real life, and so on). The very informal nature of the medium means that it is generally not conducted in a businesslike manner; it is more like our personal interactions and notes. When the social glue of an office becomes less business-oriented, it can lead to inappropriate advances, commentary, and exposure. Outlining inappropriate use of IM, as with any technology, should be part of the general HR policy of a company, and correct business use should be part of a regular regimen of business conduct training.

Factor #11

What unintended exposure could the company face via IM? Which populations have this information and require special training, monitoring, or protection?

Make sure that your company has a strategy for categorization and management of sensitive information, in particular personally identifiable information, trade secrets, and material insider information.

Regulatory Concerns

Last, but far from least, are the things that simply must be protected for legal reasons. In an age where customer information is a responsibility, not a privilege, where credit-card numbers and Social Security numbers are bartered and traded and insider trading can occur in real time (sometimes over IM), it is imperative that regulatory concerns be addressed in an IM policy. If you can't implement governance policies over IM technology, you might have to ban IM use until such time as you can govern it effectively—and you very well may have to take steps to actively root out and remove IM applications, with drastic consequences for those who break the company's IM policy. Examples of these are common in financial institutions, HR organizations, and healthcare organizations.

Factor #12

Do you have regulatory requirements that require a certain IM posture and policy?

No matter how attractive the technology, you may not be able to adopt IM if the regulatory concerns aren't addressed. If you absolutely need it, the project to adopt compliant IM will be driven higher in the priority queue; but the basic regulatory requirement and penalties could be prohibitive if this isn't done with utmost care and attention.

Remember also that some countries have explicit regulations about monitoring employees. In some jurisdictions in Europe and Asia in particular, it is *illegal to monitor employee behavior and actions.* This may seem alien to some in the United States, but multinationals and companies in other regions must conform to employee rights requirements.

10. A good source on these is found at AOL (www.aim.com/acronyms.adp).

6. COMMON IM APPLICATIONS

IM is a fact of life. Now it is time to decide which applications and infrastructures your company can and will be exposed to. You most likely will want to create a policy and to track various uses of IM and develop a posture and educational program about which ones are used in which contexts. You will want to review common IM applications in the consumer or home user domain because they will find their ways into your environment and onto your assets. For example, many people install IM applications for personal use on laptops that they then take out of the company environment; they aren't using them at work, but those applications are on systems that have company intellectual property and material on them and they are used on insecure networks once they leave the building.

Consumer Instant Messaging

Numbers of subscribers are hard to come by in a consistent manner, although some analyst firms and public sites present disparate numbers. Wikipedia has a current view and commentary on relative sizes of IM networks and concentrations that are worth examining and verifying in a more detailed fashion. The major IM programs are AIM at 100 million, Yahoo! Messenger at 248 million, Windows Live Messenger/MSN at 330 million users, Skype at 882 million, and Tencent at a staggering 900 million (which is up enormously from the first edition of this book). There is also a good comparison of the technologies and infrastructure in use with various tools as well. Others include a host of smaller applications such as ICQ (at 50 million) continue to proliferate.

It is important to keep in mind who owns the infrastructures for private IM applications. In effect, the IM backbone passes information in the clear (unless an encryption program is used, and the owners of the infrastructure can see and collect data on who is communicating with whom, how, and what they are saying.

It could, for instance, with respect to quarterly earnings or an investigation or lawsuit, be materially important to know with whom the CFO is communicating and at what times. As a result, companies are well advised to educate employees on the risks of IM in general and the acceptable uses for certain applications. It may be acceptable to talk to your husband or wife on Yahoo! or QQ, but is it acceptable to talk to your lawyer that way?

Enterprise Instant Messaging

Some companies, such as IBM and Microsoft, offer IM solutions for internal use only. These are readily deployed and allow for good, real-time communications within the company. They of course do not address the issues of bridging communications with the outside world and the general public, but they are good for meeting some needs for improved productivity and efficiency that are clearly business related. The risk that these pose is in complacency—assuming that the IM application is exclusively used within the organization. Very often, they are used from public places or from private homes and even in some cases from employee-owned assets. As such, the ecosystem for remote access should be carefully considered.

Instant-Messaging Aggregators

There are some programs, such as Trillian,[11] for pulling together multiple IM applications. The danger here is similar to many applications that aggregate passwords or information: They should be legitimate companies, such as Cerulean Studios, with real privacy and security policies. Many illegitimate applications pose as IM aggregators, especially "free" ones, and are really in the business of establishing a spyware presence on PCs, especially corporate-owned PCs. To be clear, there are real, legitimate IM aggregators with real value, and you should look to do business with them, read their end-user license agreements (EULAs), and deploy and manage them correctly. There are also *illegitimate* companies and organizations that manufacture spyware but that pose as IM aggregators; these will come into your environment via well-meaning end users.

Most *illegitimate* applications should be caught with antispyware applications (note that some antivirus applications have antispyware capabilities; verify that this is the case with your vendor) that are resident on PCs, but there are some basic steps you should make sure that your security policies and procedures take into account:

- Make sure that you have antivirus and antispyware software, that it is up to date and that it is active.
- Make sure that end users know the risks of these applications, especially on non-corporate systems (home or user-owned systems).
- Make sure that you survey communications into and out of the network for "phone home," especially encrypted communications and that you have a standard policy and procedure on what course of action to take should suspicious communications be discovered.

Backdoors: Instant Messaging Via Other Means (HTML)

Some IM applications have moved to HTML-based integrations with their network. The reason is obvious: This

11. Manufactured by Cerulean Studios: http://www.ceruleanstudios.com.

is a way around the explicit IM protocols being blocked on corporate networks. Employees want to keep using their IM tools for personal or professional reasons, and they are finding workarounds. The obvious counter to this is HTML content filtering, especially at the gateways to networks. If your policy disallows IM, make sure the content-filtering blacklists are sensitive to IM IP addresses and communications. Many IM applications will actively scan for ports that are available on which they can piggyback communications, meaning that if you have any permissive rules for communications, the IM application will find it.

Mobile Dimension

Computing platforms and systems keep getting smaller and converging with their larger cousins; PDAs and phones are everywhere, and most major IM networks have an IM client for BlackBerry, cell phones, and the like. On corporate-owned assets with the latest generation of mobile technologies, it is fairly simple to lock down these applications to conform to the corporate IM policy. In some instances, however, it is more complex, especially in situations where PDAs are employee-owned or managed. In these cases, you actually have a larger potential problem and need a PDA and phone policy; the IM policy is secondary to that.

7. DEFENSIVE STRATEGIES

There are four basic postures that you can take within your company with respect to IM (actually this applies to all end-user applications more generally, although it needs to be rationalized for IM in particular):

- *Ban all IM.* This is the least permissive and most likely to fail over time. It is normally only advisable in cases of extremely high risk and in businesses that are very resistant to technology. This will be the hardest to enforce socially if not technically.
- *Allow internal IM.* This is the most common first step, but it demands a careful understanding and policies and procedures to enforce the ban on *external* or consumer IM.
- *Allow all IM.* Outright allowing all IM is not a common first policy, though some companies on due consideration may consider it.
- *Create a sophisticated IM policy.* This is the most difficult to do, but a sophisticated and granular IM policy, integrated with classic security measures, asset management, and a rigorous information policy, is the hallmark of a mature security organization. Incidentally, many of these exist already. It is not necessary to reinvent all of them if these sorts of policies have already been worked through and are a Web search away.

8. INSTANT-MESSAGING SECURITY MATURITY AND SOLUTIONS

Companies will likely go through an evolution of the security policy with respect to IM. Many (particularly older companies) begin with a ban and wind up over time settling on a sophisticated IM policy that takes into account asset policies, information policies, human behavior, risk, and corporate goals around employee satisfaction, efficiency, and productivity.

Asset Management

Many asset management solutions such as CA Unicenter, IBM Tivoli, and Microsoft SMS manage systems and the software they have. They are most effective for managing corporate-owned assets; make sure that employees have the right tools, correctly licensed and correctly provisioned. They also make sure that rogue, unlicensed software is minimized and can help enforce IM applications bans as in the case of a "ban of all IM" policy or a ban on external or consumer IM.

Built-In Security

Enterprise IM applications are generally the most readily adopted of solutions within a company or organization. Many of these IM platforms and "inside the firewall" IM applications provide some built-in security measures, such as the ability to auto-block inbound requests from unknown parties. Many of these features are good for hardening obvious deficiencies in the systems, but by themselves they do not typically do enough to protect the IM infrastructure.

Keep in mind also that "inside the firewall" is often misleading; people can readily sign on to these applications via virtual private network from outside the firewall or even from home computers, with a little work. Make sure the access policies and security features built into internal applications are understood and engaged correctly.

It is also generally good to ensure that strong authentication (multifactor authentication) is used in cases where people will be gaining remote access to the internal IM application. You want to make sure that the employee in question is in fact the employee and not a family member, friend, or someone who has broken into the employee's home or hotel room.

Content Filtering

A class of relatively new security products has arisen over the past few years specifically designed to do content filtering on IM. These are still not widely adopted and, when adopted, apply to only a limited set of users. Most companies that use these tools are those with strong regulatory requirements and then only to a limited set of users who expose the company most. The most common examples are insiders in financial firms or employees who can access customer data. Real-time leaks in a regulated or privileged environment are generally the most serious drivers here.

Classic Security

The perimeter is dead—long live the Internet. It is almost hackneyed these days to say that perimeter-centric security is dead; firewalls and IDSs aren't the solution. In many ways, modern security is about proving a negative—it can't be done. Human beings seeking to do better at their jobs, to communicate with friends and family, or to actively invade and bypass security will find new ways and new vectors around existing security controls. Having said that, it is important to realize that our job as security professionals is to first remove the inexpensive and easy ways to do get around security controls and then to efficiently *raise the security bar* for getting at what matters: the information. It is important to do a real, quantitative analysis of your cost threshold for the controls you are going to put in place and the amount by which it raises the bar and compare these to the risk and likelihood of loss.

In this regard, the traditional software for perimeter security *still serves a purpose;* in fact, many of these vendors are quite innovative at adding new features and new value over time. The classic products of proxies, corporate firewalls, virtual private networks, intrusion detection, and anti-malware continue to raise the bar for the most simple and inexpensive attack vectors and for stopping inadvertent leakage. This is true of adding layered protection to IM, and the classic security products should be leveraged to raise the security bar (that is, to lower basic business risk). They won't solve the problem, but it is important to use them in a layered approach to reducing business risk.

Compliance

Some industries have strict regulations that require that information be handled in certain ways. These industries have no choice but to comply or face punitive and legal damages and increased risk to their business. It is vital to consult with auditors and compliance departments regarding the implications of IM on corporate compliance.

Also, explicitly keep in mind employee rights legislation that may prohibit monitoring employees' IM communications. There are jurisdictions in which this kind of monitoring is illegal.

Data Loss Prevention

There is a new class of data loss prevention (DLP) product that can discover, classify, categorize, monitor, and enforce information-centric policies (at endpoint, network, datacenter, and "gateway" touchpoints) for a user population—either the whole company or a subset of the workforce population. There are tradeoffs to be made among applications of this type, in particular when it comes to false positives (wrongly identifying information as sensitive) and efficiency at particular times (filtering HR information during benefits enrollment periods or filtering financial-related information at the close of a quarter). This class of product can be massively powerful for enforcing the policy as a useful tool, but its efficiency and impact on *employee* efficiency need to be carefully applied. Further, the vital discovery, classification, and categorization features should be well understood, as should monitoring and enforcement applications.

Logging

Security information and event management (SIEM) systems are only as effective as what they instrument. In combination with content-filtering and DLP, this technology can be extremely effective. The best "real-world" analogy is perhaps insider trading. It is not impossible to commit insider trading, but it isn't as widespread as it could be because the Securities and Exchange Commission (and other regulatory bodies outside the United States) has effective logging and anomaly detection and reporting functions to catch transgressors. Logging in the form of SIEM on the right controls is both a good measure for active protection and a deterrent; just be sure to mention in your education processes that this is happening, to realize the deterrence benefit.

Anomaly Detection

Going beyond even correlation in a SIEM context, it's possible to look for patterns and trends in data – neural networks, Bayesian engines and other correlation engines can be used to determine baselines, deviation from baselines and to spot anomalies. The most effective of these will also tie into a risk analysis engine and should inform authentication and authorization engines in your company. The general direction of authentication technologies

is towards establishing context, "continuous" authentication and a constant estimation of the likely risk inherent in someone whenever they do a transaction of any sort.

Archival

In conjunction with regulatory requirements, you may have either a process or audit requirement to keep logs for a certain period of time. Archival, storage, and retrieval systems are likely to form an important part of your post-event analysis and investigation and forensics policies and may actually be legally required for regulatory purposes.

9. PROCESSES

The lifeblood of any policy is the process and the people who enforce that policy. You will need a body of processes and owners that is documented and well maintained. Some of the processes you may need include, but aren't limited to, the following.

Instant-Messaging Activation and Provisioning

When someone is legitimately entitled to IM, how specifically do they get access to the application? How are they managed and supported? If you have IM, you will have issues and will have to keep the application and service current and functioning.

Application Review

Make sure that you know the state of the art in IM. Which applications have centralized structures, and what nations and private interests host these? Which applications are poorly written, contain weaknesses or, worse, have remote control vulnerabilities and are potentially Spyware?

People

Make sure your IT staff and employees know the policies and why they matter. Business relevance is the best incentive for conformity. Work on adding IM to the corporate ethics, conduct, information, and general training policies.

Revise

Keep the policy up to date and relevant. Policies can easily fall into disuse or irrelevance, and given the nature of advances in Internet technologies, it is vital that you regularly revisit this policy on a quarterly or semiannual basis. Also ensure that your policy is enforceable; a policy that is not enforceable or is counterintuitive is useless.

Audit

Be sure to audit your environment. This is not auditing in the sense of a corporate audit, although that may also be a requirement, but do periodic examinations of network traffic for sessions and traffic that are out of policy. IM will leave proprietary protocol trails and even HTML trails in the network. Look in particular for rogue gateways and rogue proxies that have been set up by employees to work around the corporate policy.

10. SUMMARY

Remember game theory with respect to your workforce and business; people will find ways to do more with the tools, networks, and systems at their disposal. They will find ways to use ungoverned technology, such as IM, to do more things with more people more efficiently. The

The 12 Factors

Factor #1: Do your employees need IM? If so, which employees need IM and *what do they need it for?*

Factor #2: Is IM important as a job satisfaction component?

Factor #3: Does IM improve or lessen efficiency?

Factor #4: Will this efficiency change over time, or is it in fact different for different demographics of my workforce?

Factor #5: Does your company have a need or dependency on IM to do business?

Factor #6: Are you considering deploying a technology or process on an IM infrastructure?

Factor #7: Does the value to the company of information and processes carried over IM represent something that is a valuable target (because it can either affect your business or realize a gain)? This should include the ability to blackmail employees and partners; can someone learn things about key employees that they could use to threaten or abuse employees and partners?

Factor #8: If the IM technology were abused or compromised, what would be the risk to the business?

Factor #9: What intellectual property, material information, corporate documents, and transaction information is at risk over IM?

Factor #10: What do transaction types and times tell people about your business? Is it okay for people to have access to this information?

Factor #11: What unintended exposure could the company face via IM? Which populations have this information and require special training, monitoring, or protection?

Factor #12: Do you have regulatory requirements that require a certain IM posture and policy?

An Agenda for Action for Regulatory Requirements and the Basic Business Assets that must be Protected

This will mean having a posture on the following items, at a minimum (Check All Tasks Completed):

_____**1.** You must have formal, written policies for each of the following:
  _____**a.** Intellectual property identification, monitoring, and protection
  _____**b.** Sensitive information identification, monitoring, and protection
  _____**c.** Entitlements by role for IM specifically
  _____**d.** Legitimate, accepted uses for IM and specifically prohibited ones (if any)
  _____**e.** Monitoring of IM traffic
  _____**f.** Enforcement of IM policies
  _____**g.** Logging of IM traffic
  _____**h.** Archival of IM logs
  _____**i.** Regulatory requirements and needs and the processes to satisfy them around IM

_____**2.** Education
  _____**a.** With respect to IM
  _____**b.** With respect to regulations
  _____**c.** With respect to intellectual property
  _____**d.** With respect to social engineering
  _____**e.** About enforcement, monitoring, and archival requirements (remember that these can have a deterrence benefit)

_____**3.** Applications
  _____**a.** Dealing with consumer IM and the applications employees will try to use
  _____**b.** Internal, enterprise IM applications
  _____**c.** Asset management

_____**4.** Processes
  _____**a.** Provisioning IM and accounts
  _____**b.** Deprovisioning (via asset management processes) illegal IM clients
  _____**c.** Revoking IM entitlements and accounts

_____**5.** Do you have basic security hygiene configured correctly for an environment that includes IM?
  _____**a.** Asset management software
  _____**b.** Firewalls and proxies
  _____**c.** Intrusion detection systems
  _____**d.** Anti-malware
  _____**e.** Virtual private networks and remote access
  _____**f.** Strong authentication
  _____**g.** Authorization

_____**6.** Advanced security
  _____**a.** Monitoring and enforcement with DLP
  _____**b.** Monitoring and SIEM
  _____**c.** Anomaly and pattern detection

siren call of real-time communications is too much to resist for a motivated IT department and a motivated workforce who want to do more with the tools that are readily available to them.

Let's review a few lists and what you must consider in formulating an IM security policy—and remember that this must always be *in service* to the business. In the following sidebar, "The 12 Factors," consider the factors and the posture in which these put you and your company.

Now consider your responses to these factors in the context of your employees, your partners, your competitors, and the active threats your company will face. Next, consider the basic risks and returns and the infrastructure that you deploy:

- Where are the single points of failure?
- Where does liability lie?
- What is availability like?
- What is the impact of downtime on the business?
- What is the business risk?
- What are your disaster recovery and business continuity options?

Last, consider regulatory requirements and the basic business assets you must protect. You will most likely have to create or update your security policy to consider IM. (see checklist, "An Agenda For Action For Regulatory Requirements And The Basic Business Assets That Must Be Protected").

IM, like any other technology, can serve the business or be a risk to it. The best situation of all is where it is quantified like any other technology and helps promote

Acme Inc.'s Answers to the 12 Factors

Factor #1: Do your employees need IM? If so, which employees need IM and *what do they need it for?*

Yes! All nonline working employees should have IM to allow for increased internal communications.

Factor #2: Is IM important as a job satisfaction component? Yes!

Factor #3: Does IM improve or lessen efficiency? IM should improve efficiency by allowing employees to get immediate answers/results and to be able to pull groups together quickly, compared to emails.

Factor #4: Will this efficiency change over time, or is it in fact different for different demographics of my workforce? Efficiency should grow as adoption and comfort levels with IM technologies grow.

Factor #5: Does your company have a need for or dependency on IM to do business?

IM cannot be used for external business transactions or discussions.

Factor #6: Are you considering deploying a technology or process on an IM infrastructure?

Yes. We would need to implement an internal tool to perform IM services.

Factor #7: Does the value to the company of information and processes carried over IM represent something that is a valuable target (because it can either affect your business or realize a gain)? This should include the ability to blackmail employees and partners; can someone learn things about key employees that they could use to threaten or abuse employees and partners?

Yes. All IM communications must remain internal.

Factor #8: If the IM technology were abused or compromised, what would be the risk to the business? Data loss: intellectual property.

Business plan loss: Sensitive information that we can't afford to let the competition see.

Customer data theft: Some Personally Identifiable Information (PII), but all customer-related information is treated as PII.

Factor #9: What intellectual property, material information, corporate documents, and transaction information is at risk over IM?

All internal data would be at risk.

Factor #10: What do transaction types and times tell people about your business? Is it okay for people to have access to this information?

Data will always remain on a need-to-know basis and the IM implementation must not result in the loss of data.

Factor #11: What unintended exposure could the company face via IM? Which populations have this information and require special training, monitoring, or protection? Unintentional internal transfer of restricted data to internal staff without the required internal clearances.

Factor #12: Do you have regulatory requirements that require a certain IM posture and policy? We are under PCI, HIPAA, ISO 27001, and SAS70 Type II guidelines.

the ability to attract talent and keep it while serving the business—driving more business with more people more efficiently and while minimizing risk for business return.

Example Answers to Key Factors

Let's take the example of Acme Inc., as shown in the sidebar, "Acme Inc.'s Answers to the 12 Factors." Acme is a publicly traded company that has international offices and groups that span geographies.

Giving answers to these simple questions mean that the scope of risk and the business relevance is known. These answers can now be used to formulate a security policy and begin the IT projects that are needed for enforcement and monitoring.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? When considering IM, it is important to realize that it is first and foremost a technology; it is not a goal in and of itself.
2. True or False? IM is a technology in a continuum of advances (q.v.) that have arisen for communicating and collaborating over a local area network.
3. True or False? Perhaps the most important "law" with respect to networks and for instant messaging is Metcalfe's Law, which states that the value of a telecommunications network increases exponentially with a linear increase in the number of users. (Actually, it states that it is proportional to the square of the users on the network.)
4. True or False? Whenever gains or losses can be quantified for a given population, game theory does not apply.
5. True or False? Whether you work in an IT department or run a small company, your employees have things they need to do: process orders, work with peers, manage teams, talk to customers and to partners. ΓM is a tool they can and will use to do these things.

Multiple Choice

1. Employees without _____ will seek to get it by abusing backdoors or processes to get this entitlement.
   - **A.** XM
   - **B.** IMS
   - **C.** IM
   - **D.** EM
   - **E.** EXO
2. Some companies have taken a bold step and use _________ for actual business processes?
   - **A.** Metcalfe's Law
   - **B.** Malicious threat
   - **C.** Spyware
   - **D.** IM infrastructure
   - **E.** APT
3. Like any form of software (or hardware), IM applications and infrastructure are subject to __________and weaknesses from poor configuration and implementation.
   - **A.** Evolution
   - **B.** Residue class

C. Vulnerabilities
D. Certification Authority
E. Security

4. A _______ attack is a class of attack in which a third party acts as a legitimate or even invisible broker.
   A. Trojan horse
   B. X-in-the-middle
   C. Man-in-the-middle
   D. keylogger
   E. tap
5. What is the practice of fooling someone into giving up something they wouldn't otherwise surrender through the use of psychological tricks?
   A. Phishing
   B. IM identity
   C. Knowledge
   D. Intellectual property
   E. Social engineering

Privacy on the Internet

Marco Cremonini
Università degli Studi di Milano

Chiara Braghin
Università degli Studi di Milano

Claudio Agostino Ardagna
Università degli Studi di Milano

1. PRIVACY IN THE DIGITAL SOCIETY

Privacy in today's digital society is one of the most debated and controversial topics. Many different opinions about what privacy actually is and how it could be preserved have been expressed, but still we can set no clear-cut border that cannot be trespassed if privacy is to be safeguarded.

The Origins, the Debate

As it often happens when a debate heats up, the extremes speak louder and, about privacy, the extremes are those that advocate the ban of the disclosure of whatever personal information and those that say that all personal information is already out there, therefore privacy is dead. Supporters of the wide deployment and use of anonymizing technologies are perhaps the best representatives of one extreme. However, these are just the extremes; in reality privacy in the digital society is a fluid concept that such radical positions cannot fully contain. It is a fact that even those supporting full anonymity recognize that there are several limitations to its adoption, either technical or functional. On the other side, even the most skeptical cannot avoid dealing with privacy issues, either because of laws and norms or because of common sense. Sun Microsystems, for example, is actually supporting privacy protection and is a member of the Online Privacy Alliance, an industry coalition that fosters the protection of individuals' privacy online.

Looking at the origins of the concept of privacy, Aristotle's distinction between the public sphere of politics and the private sphere of the family is often considered the root. Much later, the philosophical and anthropological debate around these two spheres of an individual's life evolved. John Stuart Mill, in his essay, *On Liberty*, introduced the distinction between the realm of governmental authority as opposed to the realm of self-regulation. Anthropologists such as Margaret Mead have demonstrated how the need for privacy is innate in different cultures that protect it through concealment or seclusion or by restricting access to secret ceremonies.

More pragmatically, back in 1898, the concept of privacy was expressed by U.S. Supreme Court Justice Brandeis, who defined privacy as "The right to be let alone."[1] This straightforward definition represented for decades the reference of any normative and operational privacy consideration and derivate issues and, before the advent of the digital society, a realistically enforceable ultimate goal. Internet has changed the landscape because the very concept of being let alone while interconnected becomes fuzzy and fluid.

In 1948, privacy gained the status of fundamental right of any individual, being explicitly mentioned in the United Nations Universal Declaration of Human Rights (Article 12): "No one shall be subjected to arbitrary interference with his privacy, family, home or correspondence, nor to attacks upon his honor and reputation. Everyone has the right to the protection of the law against such interference or attacks."[2] However, although privacy has been recognized as a fundamental right of each individual, the Universal Declaration of Human Rights does not explicitly define what privacy is, except for relating it to possible interference or attacks.

About the digital society, less rigorously but otherwise effectively in practical terms, in July 1993, *The New Yorker* published a brilliant cartoon by Peter Steiner that since then has been cited and reproduced dozen of times to refer to the supposed intrinsic level of privacy—here in the sense of anonymity or hiding personal traits—that can

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00042-8

be achieved by carrying out social relations over the Internet. That famous cartoon shows one dog that types on a computer keyboard and says to the other one: "On the Internet, no one knows you're a dog."[3] The Internet, at least at the very beginning of its history, was not perceived as threatening to individuals' privacy; rather, it was seen as increasing it, sometimes too much, since it could easily let people disguise themselves in the course of personal relationships. Today that belief may look naïve with the rise of threats to individual privacy that have accompanied the diffusion of the digital society. Nevertheless, there is still truth in that cartoon because, whereas privacy is much weaker on the Internet than in real space, concealing a person's identity and personal traits is technically even easier. Both aspects concur and should be considered.

A commonly used definition of privacy is by Alan Westin: "Privacy is the claim of individuals, groups and institutions to determine for themselves, when, how and to what extent information about them is communicated to others."[4] The definition is rather generic since it does not specify what kind of personal information is to be considered. In the digital society, in particular in the context of network communication, the information can be the identity of the sender, the identity of the receiver, the identity of both, the fact that there is a communication is ongoing, the host/cell/location of the participants taking part to the communication, etc. In order to address these different aspects of privacy, some terms are often used in place of privacy. In [5,6] the differences among *anonymity, unobservability*, and *unlinkability* are pointed out. In the digital society scenario, anonymity is defined as the state of not being identifiable, unobservability as the state of being indistinguishable, and unlinkability as the impossibility of correlating two or more actions/items/pieces of information.

Privacy, however defined and valued, is a tangible state of life that must be attainable in both the physical and the digital society. The reason that in the two realms—the physical and the digital—privacy behaves differently has been widely debated, too, and many of the critical factors that make a difference in the two realms, the impact of technology and the Internet, have been spelled out clearly. However, given the threats and safeguards that technologies make possible, it often remains unclear what the goal of preserving privacy over the Internet should be—being that extreme positions are deemed unacceptable.

Lessig, in his book *Free Culture*,[7] provided an excellent explanation of the difference between privacy in the physical and in the digital world: "The highly inefficient architecture of real space means we all enjoy a fairly robust amount of privacy. That privacy is guaranteed to us by friction. Not by law [. . .] and in many places, not by norms [. . .] but instead, by the costs that friction imposes on anyone who would want to spy. [. . .] Enter the Internet, where the cost of tracking browsing in particular has become quite tiny. [. . .] The friction has disappeared, and hence any 'privacy' protected by the friction disappears, too."

Thus, privacy can be seen as the friction that reduces the spread of personal information, that makes it more difficult and economically inconvenient to gain access to it. The merit of this definition is to put privacy into a relative perspective, which excludes the extremes that advocate no friction at all or so much friction to stop the flow of information. It also reconciles privacy with security, being both aimed at setting an acceptable level of protection while allowing the development of the digital society and economy rather than focusing on an ideal state of perfect security and privacy.

Privacy Threats

Threats to individual privacy have become publicly appalling since July 2003, when the California Security Breach Notification Law [8] went into effect. This law was the first one to force state government agencies, companies, and nonprofit organizations that conduct business in California to notify California customers if personally identifiable information (PII) stored unencrypted in digital archives was, or is reasonably believed to have been, acquired by an unauthorized person.

The premise for this law was the rise of *identity theft*, which is the conventional expression that has been used to refer to the illicit impersonification carried out by fraudsters who use PII of other people to complete electronic transactions and purchases. The California Security Breach Notification Law lists as PII: Social Security number, driver's license number, California Identification Card number, bank account number, credit- or debit-card number, security codes, access codes, or passwords that would permit access to an individual's financial account (see checklist, "An Agenda For Action For Protecting One's Identity"). By requiring by law the immediate notification to the PII owners, the aim is to avoid direct consequences such as financial losses and derivate consequences such as the burden to restore an individual's own credit history. Starting on January 1, 2008, the data security breach notification law in California also applies to medical information and health insurance data.

Besides the benefits to consumers, this law has been the trigger for similar laws in the United States—today, the majority of U.S. states have one—and has permitted the flourishing of regular statistics about privacy breaches, once almost absent. Privacy threats and analyses are now widely debated, and research focused on privacy problems has become one of the most important.

An Agenda for Action for Protecting One's Identity

You'll want to protect the privacy of your personal information while you're online. Here's a checklist of some of the most important things you can do to protect your identity and prevent others from easily getting your personal information: (Check All Tasks Completed):

_____1. Check a site's privacy policy before you enter any personal information and know how it will be used.

_____2. Make sure you have a secure internet connection, by checking for the unbroken key or closed lock icon in your browser, before you enter any personal information onto a webpage.

_____3. Only give a credit card number when buying something.

_____4. Register your credit cards with your card provider's online security services, such as Verified by Visa and MasterCard SecureCode.

_____5. Use just one credit card for online purchases; if possible, use an account with a low spending limit or small available balance.

_____6. Don't use a debit card for your online purchases. Credit cards are better because bank-provided security guarantees apply to credit cards, so an unauthorized charge is limited to $50.

_____7. Don't select the "remember my password" option when registering online.

_____8. Change your passwords every 60 to 90 days and don't use personal information as your password, instead use a string of at least five letters, numbers and punctuation marks.

_____9. Don't store your passwords near your computer or in your purse or wallet.

_____10. Don't give more information than a site requires.

_____11. Keep your anti-virus software up-to-date to reduce the risk of malicious code running on your PC.

_____12. Don't go online unless you have a personal firewall enabled to add a layer of protection to your PC by stopping unknown connections to your PC.

_____13. Don't reply directly to e-mail messages asking for personal information.

_____14. Type web addresses directly into your web browser instead of clicking on e-mail links.

_____15. Get anti-virus and anti-spam filtering software and keep it up to date by using its automatic update feature, if your service provider or employer doesn't provide it for you.

_____16. Check out online retailers' ratings at BizRate and the Better Business Bureau and the before buying.

The DataLossDB, maintained by the Open Security Foundation, [9] publishes one of the most complete references for privacy breaches and data losses, recording incidents involving data losses back from 2003 to date.

Looking at the largest incidents, the magnitude of some breaches is astonishing: In 2009, about 130 million records were lost by Heartland Payment Systems, USA; in 2007, about 94 million records were hacked at TJX stores in the United States; in 2011, the target was Sony Corp. and its 77 million customer's records. Many other incidents in the dozen of million size are recorded and have gained the headlines on the press, involving all sort of confidential information managed by very different kind of organizations. Most of the incidents have been consequence of hacking from outside the corporate network, but with notable exceptions. In 2004, an employee of America Online Inc. stole 92 million email addresses and sold them to spammers; in 2006 a computer containing about 26 million personal records of the U.S. Department of Veterans Affairs was stolen, in 2007 two CDs were lost containing the entire HM Revenue and Customs (GB) child benefit database (about 25 million records) and 7 million banking details. Similarly, lost tape backups or other storage media containing million of personal records were the reason for severe data loss incidents in 2008 at T-Mobile, at Deutsch Telekom company, at LaSalle Bank, USA, and at GS Caltex in South Korea.

It is interesting to note that the existence of criminals looking after huge archives of personal data is not a phenomenon that appeared with the advent of the Internet and modern interconnected digital networks. In 1984, hackers accessed a credit-reporting database, likely managed on mainframe systems, at TRW Inc. containing 90 million records, and in 1986, document about 16 million vital records of Canadian taxpayers was stolen from Toronto's District Taxation Center.

Whereas these incidents are the most notable, the phenomenon is distributed over the whole spectrum of breach sizes. Hundreds of privacy breaches are reported in the order of a few thousand records lost and all categories of organizations are affected, from public agencies, universities, banks and financial institutions, manufacturing and retail companies, and so on. To this end, it is interesting to quote the authors of the 2011 Data Breach Investigations Report by the Verizon RISK team [10]: "2010 exhibited a much more even distribution. The main factor in this shift is the lack of "mega-breaches" in our combined caseload. Many incidents involving the compromise of multi-millions of records (or more) in the last few years occurred in financial institutions. Without one or two of these skewing the results, things naturally balance out a bit more. Another factor to consider is that criminals seemed to gain interest in stealing data other than payment cards. Account takeovers, theft of IP and

other sensitive data, stolen authentication credentials, botnet activity, etc. (which are typically less mega-breachable) affected firms at increased rates in 2010". This is a precious warning not to focus excessively on that "mega-breaches" that get the headlines as the sole indicator of the status of privacy on the Internet. Even in 2010, when huge breaches did not happened (2011 is different, as we illustrated), privacy threats and incidents soared in numbers, while not in the amount of records stolen. Therefore, the threats are real and still well alive even for small-to-medium firms and organizations.

Again from the DataLossDB, we have an overview about the incidence of data breaches by breach type, business type and vector. With respect to breach type, the main ones are: 19% due to hacking; 15% due to stolen laptops; 11% due to malicious Web services; and 11% due to frauds.

A plethora of other reasons for breach, from disposal documents, media and computers to lost or missing storage media, malwares and emails are responsible for almost 40% of all breaches.

With respect to business type, incidents are distributed as follows: 49% affect business; 19% governments; 16% medical institutions; and 16% education.

Finally, the vectors mainly exploited to conduct privacy and data breaches are: 55% of incidents originate from outside an organization; 39% from inside; and 6% unknown.

It is interesting to note how, for incidents originated from inside an organization, the majority is accidental, rather than intentional. This fact points out the relevant role of mistakes, disorganization, mismanagement and all other accidental reasons that may pose severe threats to data privacy.

2. THE ECONOMICS OF PRIVACY

The existence of strong economic factors that influence the way privacy is managed, breached, or even traded off has long been recognized [11,12]. However, it was with the expansion of the online economy, in the 1990s and 2000s, that privacy and economy become more and more entangled. Many studies have been produced to investigate, from different perspectives and approaches, the relation between the two. A comprehensive survey of works that analyzed the economic aspects of privacy can be found in [13].

Two issues among the many have gained most of the attention: assessing the value of privacy and examining to what extent privacy and business can coexist or are inevitably conflicting one with the other. For both issues the debate is still open and no ultimate conclusion has been reached yet.

Privacy and Business

The relationship between privacy and business has been examined from several angles by considering which incentives could be effective for integrating privacy with business processes and, instead, which disincentives make business motivations to prevail over privacy.

Froomkin [14] analyzed what he called "privacy-destroying technologies" developed by governments and businesses. Examples of such technologies are collections of transactional data, automated surveillance in public places, biometric technologies, and tracking mobile devices and positioning systems. To further aggravate the impact on privacy of each one of these technologies, their combination and integration result in a cumulative and reinforcing effect. On this premise, Froomkin introduces the role that legal responses may play to limit this apparently unavoidable "death of privacy."

Odlyzko [15,16] is a leading author that holds a pessimistic view of the future of privacy, calling "unsolvable" the problem of granting privacy because of price discrimination pressures on the market. His argument is based on the observation that the markets as a whole, especially Internet-based markets, have strong incentives to price discriminate, that is, to charge varying prices when there are no cost justifications for the differences. This practice, which has its roots long before the advent of the Internet and the modern economy—one of the most illustrative examples is 19th-century railroad pricing practices—provides relevant economic benefits to the vendors and, from a mere economic viewpoint, to the efficiency of the economy. In general, charging different prices to different segments of the customer base permits vendors to complete transactions that would not take place otherwise. On the other hand, the public has often contrasted plain price discrimination practices since they perceive them as unfair. For this reason, many less evident price discrimination practices are in place today, among which bundling is one of the most recurrent. Privacy of actual and prospective customers is threatened by such economic pressures toward price discrimination because the more the customer base can be segmented—and thus known with greatest detail—the better efficiency is achieved for vendors. The Internet-based market has provided a new boost to such practices and to the acquisition of personal information and knowledge of customer habits.

More pragmatically, some analyses have pointed out that given the current privacy concerns, an explicitly fair management of customers' privacy may become a positive competitive factor [17]. Similarly, Hui et al. [18] have identified seven types of benefits that Internet businesses can provide to consumers in exchange for their personal information.

Privacy and the Web

With respect to the often difficult relation between business goals and privacy requirements, a special attention should be given to Web-based business and the many tools and mechanisms that have been developed to improve the knowledge about customers, their habits and preferences in order to offer to them purchase suggestions and personalized services. The drawback of such business goals is the spread of profiling and the inevitable erosion of customers and users privacy.

Despite the hype that from time to time involves popular search engines like Google or digital social networks like Facebook for their practices of collecting huge amount of information about users accessing their services, detailed and comprehensive analyses of the data collection and management activity on the Internet are still a few and often focused on one specific, while relevant, company.

One of the most informative analysis was published by Krishnamurthy and Wills at the World Wide Web Conference of 2009 [19]. In their work, they reported the results of a study spanning over several years and focused on the technical ways by which third-party aggregators acquire data and the depth of user-related information acquired. The choice of third-party aggregators is useful, because if web sites and services collecting user data are countless, third-party aggregators are a few.

The common technique adopted to track users is to use a cookie, which, in short, is a text file containing information about the user's access to a web service, often encoded in opaque formats, that a web server sends to a client, the client stores locally through its web browser and he exchanges with the server in case of further connections to the same server. Javascript, is the other main technique for tracking users: being code executed at client's side, they have access to information stored by the browser. The two mechanisms provide first- (in case of web-based services like ecommerce sites) and third-party aggregators recording many behavioral information, which, together with physical information like IP addresses, permit to identify users when surfing through the catalogue of an ecommerce site, correlate accesses to different sites and, in general, provide web analytics information about traffic measurements, user profiling and geolocation identification.

From the mentioned study, one notable result is that the top-10 third-party aggregators serve up to 80% of first-party servers analyzed. Interestingly, the authors observe that due to the raising concerns about privacy, modern web browsers now provide means to block third-party Javascript and cookies, but, as expected, the arms race between users profiling and privacy never settle down and tracking techniques are evolving to bypass those new limitations. In particular, being first-party scripts and cookies still usually allowed, being them the key to an improved user experience and variety of functionality, third-party aggregators are more and more "hiding" their content in first-party servers. Data examined by the study confirm this, exhibiting a striking growth of first-party cookies, Javascript and hidden third-party objects in the timeframe considered. Therefore, it is safe to conclude that, despite new tools and features aimed at privacy protection, blocking third-party content used for tracking users is extremely difficult, without severely impair the user experience.

Considering the limitations that affect technical means in protecting privacy, it is natural to turn the attention to regulations and guidelines too. One example of guidelines is the "Guide to Protecting the Confidentiality of Personally Identifiable Information (PII)" published by the National Institute for Standard and Technology (NIST) in 2010 [20]. The aim is "to assist Federal agencies in protecting the confidentiality of personally identifiable information (PII) in information systems". It is inspired by the Fair Information Practices, which are the principles underlying most privacy laws and privacy best practices. This publication by NIST consists of a comprehensive set of guidelines, merging consideration about information security and privacy, mostly focused on preventing frauds or massive data breaches. With regard to profiling and tracking, however, the NIST guidelines seem ineffective.

The case of the new proposed regulation by the European Union [21] is different. Being still a proposal, it may be subject to changes, amendments and its adoption delayed; therefore only preliminary considerations are possible. However, the overall rational seems clear. First, the regulation is aimed at establishing a uniform legislation among all European member states, resolving the current heterogeneity of approaches that leads to different practices and privacy protection levels. Then, it mandates a notification procedure in case of data breach, similar, in the spirit, to the many US states legislations. Finally, and most pertinent to the issues discussed in the present section, it remarkably reinforces the *opt-in* approach (i.e., this means that by default, personal information could not be acquired and managed by first- and third-parties unless the user explicitly express his/her consent, and it is opposed to the *opt-out* approach generally adopted in the USA) and imposes strong management requirements to first- and third-parties. More in particular, the proposed regulation is driven by the assumption that personal data belong and still fully belong to data owners even when collected by first- and third-parties. As a consequence, the regulation has several prescriptions about the extent of knowledge that data owners should be provided with from organizations collecting their data, the full right to inspect, modify and

delete personal data stored and even transmitted to others by those organizations, and even prescriptions about the provisioning of an European-based support service by data collectors. Therefore, the new EU regulation, if approved in the current form, could sensibly interfere with the practices adopted by data aggregators and first-parties for tracking and profiling users. However, given its status, it is still early to draw firm conclusions about its effectiveness and real impact in the arms race between business and privacy requirements.

3. PRIVACY-ENHANCING TECHNOLOGIES

Technical improvements of Web and location technologies have fostered the development of online applications that use the private information of users (including physical position of individuals) to offer enhanced services. The increasing amount of available personal data and the decreasing cost of data storage and processing makes it technically possible and economically justifiable to gather and analyze large amounts of data. In this context, users are much more concerned about their privacy, which has been recognized as one of the main reasons that prevents users from using the Internet for accessing online services. A number of useful privacy-enhancing technologies (PETs) have been developed for dealing with privacy issues, and previous works on privacy protection have focused on a wide variety of topics [22−26]. In this section, we discuss the privacy protection problem in three different contexts. We start by giving an overview of languages and approaches for the specification of access control policies in distributed networks; we then discuss languages and solutions for the definition of privacy-aware access control policies and privacy preferences in distributed networks; we finally describe the problem of protecting privacy in mobile and pervasive environments, and we give an overview of solutions for preserving the location privacy of the users from different perspectives [27].

Access Control Models and Languages

Access control systems have been introduced for regulating and protecting access to resources and data owned by parties. Originally, access control models and languages have been defined for centralized and closed environments: users were assumed to be known by the system, and to be identified and authenticated before any authorization process could start. The advent of distributed environments has changed the overall scenario making the above assumptions not possible and traditional access control inapplicable. In an open scenario, in fact, the users are usually not known to the server a-priori and, therefore, identification and authentication are not always possible/wanted. Suitable access control models and languages need to depart from identification and authentication, and to provide a solution that fits the requirements of an open scenario.

Recent works have focused on the definition of attribute-based and credential-based access control, where authorization policies specify the set of attributes and credentials that a user must possess, or conditions over credentials and attributes that a user needs to satisfy to access a resource. In this context, credential-based languages refer to those solutions that use properties of the users, included in credentials signed by third parties, to evaluate access control policies. In general, credentials are characterized by a type (Identity Card), a unique identifier, and an issuer (US government), and certify a set of properties for the user ($FirstName = \text{John}$, $LastName = \text{Doe}$). Similarly, attribute-based languages refer to those solutions that evaluate policies using attributes that are self-certified by the owner, without a signature made by a third party. Several different models and languages have been defined, prescribing access decisions on the basis of some properties that the requesting party may have. First, logic-based languages ([28−31]) have been proposed with the main goal of providing high-expressive solutions allowing the definition of policies that well adapt to the dynamics and complexity of distributed environments. However, although highly expressive and powerful, logic languages are difficult to adopt in practice especially in a distributed scenario where simplicity, interoperability, and easiness of use are fundamental requirements. [32−34] In addition to frameworks and solutions supporting logic-based access control policies, different automated trust negotiation approaches [35−37] have been developed to establish trust between unknown parties. A trust negotiation is a bidirectional exchange of requests and responses between two parties to the aim of establishing trust by incremental data disclosure. Trust negotiation research has investigated algorithms and protocols that *i)* allow a party to select credentials that have to be released to the counterpart and *ii)* protect sensitive information in credentials and/or policies during the negotiation process. In general, trust negotiation protocols provide low performance, with high overhead, and are therefore not suitable for many distributed use cases. The research community has then focused on the definition of access control models and languages that support the requirements of distributed environments, and address the issues of logic-based languages and trust negotiation approaches.

The *eXtensible Access Control Markup Language (XACML)*[38], which is the result of a standardization effort by OASIS, provides an attribute-based access control solution that balances between expressivity and simplicity, is flexibile and extensible, and integrates well with open environments. XACML proposes an XML-based language to express and interchange access control

policies, defines an architecture for the evaluation of policies, and specifies a communication protocol for messages interchange.

Main features of XACML are: *(1) policy combination*, a method for combining policies on the same resource independently specified by different entities; *(2) combining algorithms*, different algorithms representing ways of combining multiple decisions into a single decision; *(3) attribute-based restrictions*, the definition of policies based on properties associated with subjects and resources rather than on their identities; *(4) multiple subjects*, the definition of more than one subject relevant to a decision request; *(5) policy distribution*, policies can be defined by different parties and enforced at different enforcement points; *(6) implementation independence*, an abstraction layer that isolates the policy-writer from the implementation details; and *(7) obligations*, a method for specifying the actions that must be fulfilled in conjunction with the policy enforcement.

Focusing on the language, XACML is based on a model providing a formal representation of policies. Each XACML policy has an element *Policy* or *PolicySet* as root, which in turn may contain other *Policy* or *PolicySet* elements. Each *Policy* element is composed by a *Target* that evaluates policy applicability to a request, a set of *Rule* that corresponds to positive authorizations (i.e., with attribute *effect* = permit) or negative authorizations (i.e., with attribute *effect* = deny), a set of *Obligation* specifying actions to be done during the enforcement of an access decision, and a rule combing algorithm (attribute *RuleCombiningAlgId*) that establishes how conflicting decisions taken by different rules can be reconciled in a single decision (i.e., deny overrides, permit overrides, first applicable, only one applicable).

Today, XACML is considered as the de-facto standard for attribute-based access control in distributed environments and is adopted in many different scenarios. In addition, although the XACML language is not specifically designed for managing privacy, it has represented a relevant innovation in the field of access control policies and has set the basis for the definition of many authorization languages with enhanced functionalities, including support for anonymity, trust negotiation, credentials, complex conditions (recursion, delegation, chain of trust), dialog management [39–41].

Languages for Privacy-Aware Access Control and Privacy Preferences

The importance gained by privacy requirements has brought with it the definition of access control models that are enriched with the ability of supporting privacy requirements. These enhanced access control models encompass two privacy aspects: to guarantee the desired level of privacy of information exchanged between different parties by controlling the access to services/resources, and to control all secondary uses of information disclosed for the purpose of access control enforcement. Users requiring access to a server application need then to protect access to their personal data by specifying and evaluating privacy policies.

The most important proposal in this field is the *Platform for Privacy Preferences Project* (P3P), a World Wide Web Consortium (W3C) project aimed at protecting the privacy of users by addressing their need to assess that the privacy practices adopted by a server provider comply with users' privacy requirements. The goal of P3P is twofold: *i)* to allow Web sites to state their data-collection practices in a standardized, machine-readable way, and *ii)* to provide users with a solution to understand which data will be collected and how those data will be used. To this aim, P3P allows Web sites to declare their privacy practices in a standard and machine-readable XML format known as *P3P policy*. A P3P policy contains the specification of the data it protects, the data recipients allowed to access the private data, consequences of data release, purposes of data collection, data retention policy, and dispute resolution mechanisms. Supporting privacy preferences and policies in Web-based transactions allows users to automatically understand and match server practices against their privacy preferences. Thus, users do not need to read the privacy policies at every site they interact with, but they are always aware of the server practices in data handling. The corresponding language that would allow users to specify their preferences as a set of preference rules is called a *P3P Preference Exchange Language* (APPEL)[42]. APPEL can be used by users' agents to reach automated or semi-automated decisions regarding the acceptability of privacy policies from P3P-enabled Web sites. Unfortunately, interactions between P3P and APPEL have shown that users can explicitly specify just what is unacceptable in a policy, whereas the APPEL syntax is cumbersome and error prone for users.

Other approaches have focused on the definition of access control frameworks that integrate both policy evaluation and privacy functionalities. A solution that introduced a privacy-aware access control system has been defined by Ardagna et al. [43]. This framework allows the integration, evaluation, and enforcement of policies regulating access to service/data and release of personal identifiable information, and provides a mechanism to define constraints on the secondary use of personal data for the protection of users' privacy. In particular, the following types of privacy policies have been specified:

- *Access control policies*. They govern access/release of services/data managed by the party (as in traditional access control).

- *Release policies*. They govern release of properties/credentials/personal identifiable information (PII) of the party and specify under which conditions this information can be disclosed.
- *Data handling policies*. They define how personal information will be (or should be) dealt with at the receiving parties.

An important feature of this framework is to support requests for certified data, issued and signed by trusted authorities, and uncertified data, signed by the owner itself. It also allows to define conditions that can be satisfied by means of zero-knowledge proof [44] and based on the physical position of the users [45].

Most of the research on security and privacy has focused on the server-side of the problem, while symmetric approaches have been used and implemented at the client-side to protect the privacy of the users (privacy preference definition based on policies). In the last few years, however, some solutions for privacy protection that strictly focus on clients' needs have been defined.

Privacy in Mobile Environments

The concept of *location privacy* can be defined as the right of individuals to decide how, when, and for which purposes their location information could be released to other parties. The lack of location privacy protection could be exploited by adversaries to perform various attacks [46]:

- *Unsolicited advertising*, when the location of a user could be exploited, without her consent, to provide advertisements of products and services available nearby the user position.
- *Physical attacks or harassment*, when the location of a user could allow criminals to carry out physical assaults on specific individuals.
- *User profiling and tracking*, when the location of a user could be used to infer other sensitive information, such as state of health, personal habits, or professional duties, by correlating visited places or paths.
- *Political, religious, sexual persecution and discrimination*, when the location of a user could be used to reduce the freedom of individuals, and mobile technologies are used to identify and persecute opponents.
- *Denial of service*, when the location of a user could motivate an access denial to services under some circumstances.

A further complicating factor is that location privacy can assume several meanings and introduce different requirements, depending on the scenario in which the users are moving and on the services the users are interacting with. The following categories of location privacy can then be identified:

- *Identity privacy* protects the identity of the users associated with or inferable from location information. To this purpose, protection techniques aim at minimizing the disclosure of data that can let attackers infer a user identity. Identity privacy is suitable in application contexts that do not require the identification of the users for providing a service.
- *Position privacy* protects the position of individual users by perturbing corresponding information and decreasing the accuracy of location information. Position privacy is suitable for environments where users' identities are required for a successful service provisioning. A technique that most solutions exploit, either explicitly or implicitly, consists of reducing the accuracy by scaling a location to a coarser granularity (from meters to hundreds of meters, from a city block to the whole town, and so on).
- *Path privacy* protects the privacy of information associated with users movements, such as the path followed while travelling or walking in an urban area. Several location-based services (personal navigation systems) could be exploited to subvert path privacy or to illicitly track users.

Since location privacy definition and requirements differ depending on the scenario, no single technique is able to address the requirements of all location privacy categories. Therefore, in the past, the research community, focusing on providing solutions for the protection of location privacy of users, has defined techniques that can be divided into three main classes: *anonymity-based, obfuscation-based*, and *policy-based* techniques. These classes of techniques are partially overlapped in scope and could be potentially suitable to cover requirements coming from one or more of the categories of location privacy. It is easy to see that anonymity-based and obfuscation-based techniques can be considered dual categories. Anonymity-based techniques have been primarily defined to protect identity privacy and are not suitable for protecting position privacy, whereas obfuscation-based techniques are well suited for position protection and not appropriate for identity protection. Anonymity-based and obfuscation-based techniques could also be both exploited for protecting path privacy. Policy-based techniques are in general suitable for all location privacy categories, although they are often difficult to understand and manage for end users.

Among the classes of techniques just introduced, current research on location privacy has mainly focused on supporting anonymity and partial identities. Beresford and Stajano [47] propose a method, called *mix zones*, which uses an anonymity service based on an

infrastructure that delays and reorders messages from subscribers. Within a mix zone (an area where a user cannot be tracked), a user is anonymous, meaning that the identities of all users coexisting in the same zone are mixed and become indiscernible. Other works are based on the concept of k-anonymity [48] applied to location privacy. Bettini et al. [49] design a framework able to evaluate the risk of sensitive location-based information dissemination. Their proposal puts forward the idea that the geolocalized history of the requests submitted by a user can be considered as a quasi-identifier that can be used to discover sensitive information about the user. Gruteser and Grunwald [50] develop a middleware architecture and an adaptive algorithm to adjust location information resolution, in spatial or temporal dimensions, to comply with users' anonymity requirements. To this purpose, the authors introduced the concepts of *spatial cloaking*. Spatial cloaking guarantees k-anonymity by enlarging the area where a user is located to an area containing k indistinguishable users. Cornelius et al. [51] describe *AnonySense*, a privacy-aware architecture that implements complex applications using collaborative and opportunistic sensing by mobile devices. The proposed solution protects the privacy of the involved users by submitting sensing tasks to mobile devices in an anonymous way, and by collecting anonymized (but verified) sensed data. Chow et al. [52] provide a spatial cloaking solution for P2P environments and protocols, based on information sharing, historical location, and cloaked area adjustment schemes.

Anonymity has also been exploited to protect the path privacy of the users. Chow and Mokbel [53] provide a survey of the most advanced techniques for privacy protection in continuous LBS and trajectory data publication.

Alternatively, when the user identity is required for location-based service provision, obfuscation-based techniques have been deployed. Obfuscation is the process of degrading the quality of location information for privacy reasons. An important issue is to manage the trade-off between individual needs for high-quality information services and for location privacy. Ardagna et al. [54] define an approach based on obfuscation for protecting the location privacy of the users against malicious adversaries. The proposed solution is based on a metric called *relevance*, which models the level of location privacy, and balances location privacy with the accuracy needed for the provision of reliable location-based services. The authors introduce different obfuscation-based techniques aimed at preserving location privacy by artificially perturbing location information (modeled as planar and circular areas). These techniques, which can be used alone or in combination, degrade the location information accuracy by (1) enlarging the radius, (2) reducing the radius, and (3) shifting the center of the measured location. The robustness of the obfuscation techniques is tested against attackers with different knowledge and capabilities, to verify their suitability in a real environment. Hashem and Kulik [55] present a decentralized approach to privacy in wireless ad-hoc networks that mixes both k-anonymity and obfuscation concepts. First of all, the users obfuscate their precise location; then, they anonymize the request by transforming the obfuscated area in a k-anonymous area that contains the obfuscated area of other k-1 users. After creating the anonymous area, an algorithm selects a query requester with a near-uniform randomness, thus ensuring sender anonymity.

Finally, policy-based techniques are based on the notion of privacy policies and are suitable for all the categories of location privacy. In particular, privacy policies define restrictions that must be enforced when location of users is used by or released to external parties. As an example, the IETF Geopriv working group [56] addresses privacy and security issues related to the disclosure of location information over the Internet. The main goal is to define an environment supporting both location information and policy data.

4. NETWORK ANONYMITY

In recent years, Internet has become an essential aspect of our daily activities, thus the interest in security and privacy issues on the Internet has grown exponentially. In particular, in such a distributed environment, privacy should also imply anonymity: a person shopping online may not want her visits to be tracked, the sending of email should keep the identities of the sender and the recipient hidden from observers, and so on. That is, when surfing the Web, users want to keep secret not only the information they exchange but also the fact that they are exchanging information and with whom. Such a problem has to do with traffic analysis, and it requires ad hoc solutions. Traffic analysis is the process of intercepting and examining messages to deduce information from patterns in communication. It can be performed even when messages are encrypted and cannot be decrypted. In general, the greater the number of messages observed or even intercepted and stored, the more can be inferred from the traffic. It cannot be solved just by encrypting the header of a packet or the payload: in the first case, the packet could still be tracked as it moves through the network; the second case is ineffective as well since it would still be possible to identify who is talking to whom.

In this section, we first describe the onion routing protocol [57–59], one of the better-known approaches that is not application-oriented. Then, we provide an overview of other techniques for assuring anonymity and privacy over networks and we discuss the problem of mail anonymity.

Onion Routing and TOR

Onion routing is intended to provide real-time bidirectional *anonymous connections* that are resistant to both eavesdropping and traffic analysis in a way that is transparent to applications. That is, if Alice and Bob communicate over a public network by means of onion routing, they are guaranteed that the content of the message remains confidential and no external observer or internal node is able to infer that they are communicating.

Onion routing works beneath the application layer, replacing socket connections with anonymous connections and without requiring any change to proxy-aware Internet services or applications. It was originally implemented on Sun Solaris 2.4 in 1997, including proxies for Web browsing (HTTP), remote logins (rlogin), email (SMTP), and file transfer (FTP) and now runs on most common operating systems. It consists of a fixed infrastructure of onion routers, where each router has a long-standing socket connection to a set of neighboring ones. Only a few routers, called *onion router proxies*, know the whole infrastructure topology. In onion routing, instead of making socket connections directly to a responding machine, initiating applications make a socket connection to an onion routing proxy that builds an anonymous connection through several other onion routers to the destination. In this way, the onion routing network allows the connection between the initiator and responder to remain anonymous. Although the protocol is called onion routing, the routing that occurs during the anonymous connection is at the application layer of the protocol stack, not at the IP layer. However, the underlying IP network determines the route that data actually travels between individual onion routers. Given the onion router infrastructure, the onion routing protocol works in three phases:

- Anonymous connection *setup*
- *Communication* through the anonymous connection
- Anonymous connection *destruction*

During the first phase, the initiator application, instead of connecting directly with the destination machine, opens a socket connection with an onion routing proxy (which may reside in the same machine, in a remote machine, or in a firewall machine). The proxy first establishes a path to the destination in the onion router infrastructure, then sends an *onion* to the first router of the path. The onion is a layered data structure in which each layer of the onion (public-key encrypted) is intended for a particular onion router and contains (1) the identity of the next onion router in the path to be followed by the anonymous connection; (2) the expiration time of the onion; and (3) a key seed to be used to generate the keys to encode the data sent through the anonymous connection in both directions. The onion is sent through the path established by the proxy: an onion router that receives an onion peels off its layer, identifies the next hop, records on a table the key seed, the expiration time and the identifiers of incoming and outgoing connections and the keys that are to be applied, pads the onion and sends it to the next onion router. Since the most internal layer contains the name of the destination machine, the last router of the path will act as the destination proxy and open a socket connection with the destination machine. Note that only the intended onion router is able to peel off the layer intended to it. In this way, each intermediate onion router knows (and can communicate with) only the previous and the next-hop router. Moreover, it is not capable of understanding the content of the following layers of the onion. The router, and any external observer, cannot know *a priori* the length of the path since the onion size is kept constant by the fact that each intermediate router is obliged to add padding to the onion corresponding to the fixed-size layer that it removed.

Once the anonymous connection is established, data can be sent in both directions. The onion proxy receives data from the initiator application, breaks it into fixed-size packets, and adds a layer of encryption for each onion router in the path using the keys specified in the onion. As data packets travel through the anonymous connection, each intermediate onion router removes one layer of encryption. The last router in the path sends the plaintext to the destination through the socket connection that was opened during the setup phase. This encryption layering occurs in the reverse order when data is sent backward from the destination machine to the initiator application. In this case, the initiator proxy, which knows both the keys and the path, will decrypt each layer and send the plaintext to the application using its socket connection with the application. As for the onion, data passed along the anonymous connection appears different to each intermediate router and external observer, so it cannot be tracked. Moreover, compromised onion routers cannot cooperate to correlate the data stream they see.

When the initiator application decides to close the socket connection with the proxy, the proxy sends a destroy message along the anonymous connection and each router removes the entry of the table relative to that connection.

There are several advantages in the onion routing protocol. First, the most trusted element of the onion routing infrastructure is the initiator proxy, which knows the network topology and decides the path used by the anonymous connection. If the proxy is moved in the initiator machine, the trusted part is under the full control of the initiator. Second, the total cryptographic overhead is the same as for link encryption but, whereas in link encryption one corrupted router is enough to disclose all the data, in onion routing routers cannot cooperate to

correlate the little they know and disclose the information. Third, since an onion has an expiration time, replay attacks are not possible. Finally, if anonymity is also desired, then all identifying information must be additionally removed from the data stream before being sent over the anonymous connection. However, onion routing is not completely invulnerable to traffic analysis attacks: if a huge number of messages between routers is recorded and usage patterns analyzed, it would be possible to make a close guess about the routing, that is, also about the initiator and the responder. Moreover, the topology of the onion router infrastructure must be static and known *a priori* by at least one onion router proxy, which make the protocol little adaptive to node/router failures.

Tor [60] is the second generation onion routing. It addresses some of the limitations highlighted earlier, providing a reasonable tradeoff among anonymity, usability, and efficiency. In particular, it provides perfect forward secrecy and it does not require a proxy for each supported application protocol. Tor is also an effective *circumvention tool* (a tool to bypass Internet filtering in order to access content blocked by governments, workplaces or schools). All circumvention tools use the same core method to bypass network filtering: they proxy connections through third party sites that are not filtered themselves. [61] is a report on the usage of these tools. One of the most interesting result is the small usage of circumvention tools with respect to the number of filtering countries, explained by the authors by the fact that users are probably not aware of the existence of this kind of tools or are not able to find them.

Network Anonymity Services

Some other approaches offer some possibilities for providing anonymity and privacy, but they are still vulnerable to some types of attacks. For instance, many of these approaches are designed for World Wide Web access only; being protocol-specific, these approaches may require further development to be used with other applications or Internet services, depending on the communication protocols used in those systems.

David Chaum [62] introduced the idea of *mix networks* in 1981 (further extended subsequently, like in [63]) to enable unobservable communication between users of the Internet: it provides of sender and receiver and sender anonymity. Mixes are intermediate nodes that may reorder, delay, and pad incoming messages to complicate traffic analysis. A mix node stores a certain number of incoming messages that it receives and sends them to the next mix node in a random order. Thus, messages are modified and reordered in such a way that it is nearly impossible to correlate an incoming message with an outgoing message. Messages are sent through a series of mix nodes and encrypted with mix keys. If participants exclusively use mixes for sending messages to each other, their communication relations will be unobservable, even if the attacker records all network connections. Also, without additional information, the receiver does not have any clue about the identity of the message's sender. As in onion routing, each mix node knows only the previous and next node in a received message's route. Hence, unless the route only goes through a single node, compromising a mix node does not enable an attacker to violate either the sender nor the recipient privacy. Mix networks are not really efficient, since a mix needs to receive a large group of messages before forwarding them, thus delaying network traffic. However, onion routing has many analogies with this approach and an onion router can be seen as a real-time Chaum mix.

Reiter and Rubin [64] proposed an alternative to mixes, called *crowds*, a system to make only browsing anonymous: it aims at hiding from Web servers and third-parties information about either the user or the information she retrieves. This is obtained by preventing a Web server from learning any information linked to the user, such as the IP address or domain name, the page that referred the user to its site, or the user's computing platform. The approach is based on the idea of "blending into a crowd," that is, hiding one's actions within the actions of many others. Before making any request, a user joins a crowd of other users. Then, when the user submits a request, it is forwarded to the final destination with probability p and to some other member of the crowd with probability 1-p. When the request is eventually submitted, the end server cannot identify its true initiator. Even crowd members cannot identify the initiator of the request, since the initiator is indistinguishable from a member of the crowd that simply passed on a request from another.

Anonymous Remailers

An anonymous remailer is a system that provides sender anonymity for electronic mail. The basic idea is that a mail server receives messages and then forwards them without revealing where they originally came from. There are different types of anonymous remailer servers. A *type-0* remailer (or *Pseudonymous* remailer) removes the server address, sets a random pseudonym to the sender and sends the message to the intended recipient. In this way, the recipient may send a message back to the sender. The server keeps a list containing the matching of the pseudonyms to sender real email addresses. The remailer is vulnerable to traffic analysis, moreover if the server is compromised and an attacker is able to obtain the matching list all the senders are revealed.

Type-I remailers (or *Cypherpunk* remailers) were developed to deal with the problems highlighted above. The basic idea is the same: the remailer receive the message, removes the sender address and then send it to the recipient, but there are some changes: (i) the message may be encrypted with the remailer public key; (ii) the remailer does not keep any log that could be used to identify senders; and (iii) the message is not sent directly to the recipient but to a *chain* of remailers. In this way, a single remailer does not know both the sender and the recipient. The drawback is that it is not possible to reply to the message and that they are still vulnerable to some kinds of attack. For this reason, Type-II (or Mixmaster) and type-III (or Mixminion) remailers have been proposed, but they are not really used in practice since they require specially customized software in order to send mails.

5. SUMMARY

In this Chapter we have discussed privacy from different viewpoints, from historical to technological. The very nature of the concept of privacy requires such an enlarged perspective because it often appears indefinite, being constrained into the tradeoff between the undeniable need of protecting personal information and the evident utility, in many contexts, of the availability of the same information. The digital society and the global interconnected infrastructure eased accessing and spreading of personal information; therefore, developing technical means and defining norms and fair usage procedures for privacy protection are now more demanding than in the past.

Economic aspects have been introduced since they are likely to strongly influence the way privacy is actually managed and protected. In this area, research has provided useful insights about the incentive and disincentives toward better privacy.

We presented some of the more advanced solutions that research has developed to date, either for anonymizing stored data, hiding sensitive information in artificially inaccurate clusters, or introducing third parties and middleware in charge of managing online transactions and services in a privacy-aware fashion. Location privacy is a topic that has gained importance in recent years with the advent of mobile devices and that is worth a specific consideration.

Furthermore, the important issue of anonymity on the internet has been investigated. To let individuals surf the Web, access online services, and interact with remote parties in an anonymous way has been the goal of many efforts for years. Some important technologies and tools are available and are gaining popularity.

To conclude, whereas privacy on the internet and in the digital society does not look to be in good shape, the augmented sensibility of individuals to its erosion, the many scientific and technological efforts to introduce novel solutions, and a better knowledge of the problem with the help of fresh data contribute to stimulating the need for better protection and fairer use of personal information. For this reason, it is likely that internet privacy will remain an important topic in the years to come and more innovations toward better management of privacy issues will emerge.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Privacy in today's digital society is one of the most debated and controversial topics.
2. True or False? As it often happens when a debate heats up, the extremes speak louder and, about privacy, the extremes are those that advocate the ban of the disclosure of whatever personal information and those that say that all personal information is already out there, therefore privacy is alive.
3. True or False? Threats to individual privacy have become publicly appalling since July 2012, when the California Security Breach Notification Law [8] went into effect.
4. True or False? The existence of strong economic factors that influence the way privacy is managed, breached, or even traded off has not been recognized.
5. True or False? The relationship between privacy and business has been examined from several angles by considering which incentives could be ineffective for integrating privacy with business processes and, instead, which disincentives make business motivations to prevail over privacy.

Multiple Choice

1. With respect to the often difficult relation between business goals and privacy requirements, a special attention should be given to _______ business and the many tools and mechanisms that have been developed to improve the knowledge about customers, their habits and preferences in order to offer to them purchase suggestions and personalized services.
   A. Privacy-enhancing technology
   B. Location technology
   C. Web-based
   D. Technical improvement

E. Web Technology

2. Technical improvements of _______ and location technologies have fostered the development of online applications that use the private information of users (including physical position of individuals) to offer enhanced services?
   A. Privacy-enhancing technology
   B. Location technology
   C. Web-based
   D. Web
   E. Web Technology
3. What systems have been introduced for regulating and protecting access to resources and data owned by parties?
   A. Access control
   B. *XACML*
   C. XML-based language
   D. Certification Authority
   E. Security
4. The importance gained by privacy requirements has brought with it the definition of _____________ that are enriched with the ability of supporting privacy requirements.
   A. Access control models
   B. Languages
   C. Privacy-Aware Access Control
   D. Privacy preferences
   E. Taps
5. What govern access/release of services/data managed by the party (as in traditional access control)?
   A. Release policies
   B. Access control policies
   C. Data handling policies
   D. Intellectual property
   E. Social engineering

EXERCISE

Problem

What should I know about privacy policies?

Hands-On Projects

Project

How can I protect my privacy when shopping online?

Case Projects

Problem

How can I prevent web sites from sharing my web browsing habits?

Optional Team Case Project

Problem

How can I prevent my computer from keeping a history of where I browse?

Chapter 43

Privacy-Enhancing Technologies[1]

Simone Fischer-Hbner
Professor, Karlstad University, Karlstad/Sweden

Stefan Berthold
Karlstad University

Privacy is considered a core value and is recognized either explicitly or implicitly as a fundamental human right by most constitutions of democratic societies. In Europe, the foundations for the right to privacy of individuals were embedded in the European Convention on Human Rights and Fundamental Freedoms of 1950 (Art. 8) and the Charter of Fundamental Rights of the European Union in 2009 (Art. 7 & 8). In 1980, the OECD recognized the importance of privacy protection with the publication of the OECD Privacy Guidelines [1], which served as the foundation for many national privacy laws.

1. THE CONCEPT OF PRIVACY

Privacy as a social and legal issue has long been a concern of social scientists, philosophers, and lawyers. The first definition of privacy by legal researchers was given by the two American lawyers Samuel D. Warren and Louis D. Brandeis in their famous *Harvard Law Review* chapter "The Right to Privacy" [2], in which they defined privacy as "the right to be let alone." At that time, the risks of modern technology in the form of photography used by the yellow press to infringe privacy rights was the motivation for Warren and Brandeis's discussion of the individual's right to privacy.

In the age of modern computing, an early and often referred to definition of privacy was given by Alan Westin: "Privacy is the claim of individuals, groups and institutions to determine for themselves, when, how and to what extent information about them is communicated to others" [3]. Even though, according to Westin's definition, natural persons (humans) as well as legal persons (groups and institutions) have a right to privacy, in most legal systems, privacy is defined as a basic human right that only applies to natural persons.

In general, the concept of personal privacy has several dimensions. This chapter mainly addresses the dimension of informational privacy, which can be defined, similarly as by Westin and by the German Constitutional Court in its Census decision,[2] as the right to informational self-determination (the right of individuals to determine for themselves when, how, and to what extent information about them is communicated to others). Furthermore, so-called spatial privacy can be defined as another dimension of the concept of privacy, which also covers the "right to be let alone," where spatial privacy is defined as the right of individuals to control what is presented to their senses [4]. Further dimensions of privacy, which will, however, not be the subject of this chapter, are territorial privacy, which concerns the setting of limits on intrusion into the domestic, workplace, and other environments (public spaces), and bodily privacy, which concerns protecting a person against undue interference, such as physical searches, drug testing, or information violating his or her moral sense (see [5,6]).

Data protection concerns protecting personal data in order to guarantee privacy and is only part of the concept of privacy. Privacy, however, is not an unlimited or absolute right, because it can be in conflict with other rights or legal values and because individuals cannot participate fully in society without revealing personal data. Nevertheless, even in cases where privacy needs to be restricted, the very core of privacy still needs to be protected. For this reason, the objective of privacy and data protection laws is to define fundamental privacy principles that need to be enforced if personal data is collected, stored, or processed.

1. Parts of this work were conducted within the scope of the PetWeb II project funded by the Norwegian Research Council (NFR) and the U-PrIM project funded by the Swedish Knowledge (KK) Foundation.

2. German Constitutional Court, Census decision, 1983 (BVerfGE 65,1).

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00043-X

An Agenda for Action for Privacy-Enhancing Technologies

The Privacy-Enhancing Technology (PET) Concept: (Check All Tasks Completed)

_____**1.** Enforces making sparing use of data.
_____**2.** Makes privacy the default.
_____**3.** Transfers control to individuals.
_____**4.** Sends tags to a secure mode automatically.
_____**5.** Can prove that automatic activation of the secure mode always works.
_____**6.** Prevents eavesdropping of tag-reader communication.
_____**7.** Protects individuals from producer.
_____**8.** Protects individuals from retailer.
_____**9.** Protection includes in-store problem.
_____**10.** Protects tag in secure mode against presence-spotting.
_____**11.** Does not require individuals to take active protection measures.
_____**12.** Does not interfere with active protection measures.
_____**13.** Avoids creation and use of central database(s).
_____**14.** Avoids creation and use of databases at all.
_____**15.** Enables functionality after point-of-sale in a secure way.
_____**16.** Can be achieved without changing Radio Frequency Identification (RFID) physical technology.

2. LEGAL PRIVACY PRINCIPLES

In this section, we present an overview to internationally well-accepted, basic legal privacy principles, for which PETs implementing these principles have been developed. These principles are also part of the general EU Data Protection Directive 95/46/EC [7], which is an important legal instrument for protection of privacy in Europe, as it codifies general privacy principles that have been implemented in the national privacy laws of all EU member states and of many other states. The principles also correspond to principles of the OECD Privacy Guidelines to which we will also refer.

Legitimacy

Personal data processing has to be legitimate, which according to Art. 7 EU Directive 95/46/EC is usually the case if the data subject[3] has given his unambiguous (and informed) consent, if there is a legal obligation, or if there is contractual agreement (cf. the Collection Limitation Principle of the OECD Guidelines). The requirement of informed consent poses special challenges for the design of user interfaces (UIs) for PETs.

Purpose Specification and Purpose Binding (Also Called Purpose Limitation)

Personal data must be collected for specified, explicit, and legitimate purposes and may not be further processed in a way that is incompatible with these purposes (Art. 6 I (b) EU Directive 95/46/EC). The purpose limitation principle is of key importance for privacy protection, as the sensitivity of personal data does not only depend on how "intimate" the details are, which the personal data are describing, but is also mainly influenced by the purposes of data processing and context of use. For this reason, the data processing purposes need to be specified in advance by the lawmaker or by the data processor before obtaining the individual's consent, and personal data may later not be (mis)used for any other purposes (cf. Purpose Specification and Use Limitation Principles of the OECD Guidelines). The objective of privacy policy languages and tools is to enforce this principle.

3. A data subject is a person about whom personal data is processed.

Data Minimization

The processing of personal data must be limited to data that are adequate, relevant, and not excessive (Art. 6 I (c) EU Directive 95/46/EC). Besides, data should not be kept in a personally identifiable form any longer than necessary (Art. 6 I (e) EU Directive 95/46/EC—cf. Data Quality Principle of the OECD Guidelines, which requires that data should be relevant to the purposes for which they are to be used). In other words, the collection of personal data and the extent to which personal data are used should be minimized because obviously privacy is best protected if no personal data at all (or at least as little data as possible) are collected or processed. The data minimization principle derived from the Directive also serves as a legal foundation for PETs (see checklist: An Agenda for Action for Privacy-Enhancing Technologies). that aim at protecting "traditional" privacy goals, such as anonymity, pseudonymity, or unlinkability for users and/or other data subjects.

Transparency and Rights of the Data Subjects

Transparency of data processing means informing a data subject about the purposes and circumstances of data processing, identifying who is requesting personal data, how the personal data flow, where and how long the data are stored, and what type of rights and controls the data subject has in regard to his personal data. The Directive 95/46/EC provides data subjects with respective information rights according to its Art. 10. Transparency is a prerequisite for informational self-determination, as "a society, in which citizens can no longer know who does, when, and in which situations know what about them, would be contradictory to the right of informational self-determination."[4] Further rights of the data subjects include the right of access to data (Art. 12 (a) EU Directive 95/46/EC), the right to object to the processing of personal data (Art. 14 EU Directive 95/46/EC), and the right to correction, erasure, or blocking of incorrect or illegally stored data (Art. 12 (b) EU Directive 95/46/EC, cf. Openness and Individual Participation Principle of the OECD Guidelines).

Security

The data controller needs to install appropriate technical and organizational security mechanisms to guarantee the confidentiality, integrity, and availability of personal data (Art. 17 EU Directive 95/46/EC) (cf. Security Safeguards Principle of the OECD Guidelines). Classical security mechanisms, such as authentication, cryptography, access control, or security logging, which need to be implemented for technical data protection, will, however, not be discussed in this chapter.

In January 2012, the EU Commission published a proposal for a new EU Regulation [8], which defines a single set of modernized privacy rules and which (once the regulation is in force) will be directly valid across the EU. In particular, it includes the principle of data protection/privacy by design and by default (Art. 23), requiring building PETs already into the initial system design. Besides, the requirements of transparency for data handling and easily accessible policies (Art. 11) are explicitly included. Furthermore, the right to be forgotten (Art. 17) and a right to data portability (Art. 18) are newly included, which require technical support by appropriate PETs.

4. German Constitutional Court, Census decision, 1983 (BVerfGE 65,1).

3. CLASSIFICATION OF PETS

Privacy-enhancing technologies (PETs) can be defined as technologies that enforce legal privacy principles in order to protect and enhance the privacy of users of information technology (IT) and/or data subjects (see [9]). While many fundamental PET concepts for achieving data minimization were already introduced, mostly by David Chaum, in the 1980s (see [10–12]), the term *privacy-enhancing technologies* was first introduced in 1995 in a report on "privacy-enhancing technologies, which was jointly published by the Dutch Registratiekamer and the Information and Privacy Commissioner in Ontario/Canada [13]. PETs can basically be divided into three different classes.

The first class comprises PETs for enforcing the legal privacy principle of data minimization by minimizing or avoiding the collection and use of personal data of users or data subjects. These types of PETs provide the "traditional" privacy goals of *anonymity*, *unlinkability*, *unobservability*, and *pseudonymity*, which will be elaborated on in the next section. This class of PETs can be further divided, dependent on whether data minimization is achieved on the communication or application level. Examples for some of the most prominent data minimization technologies will be presented in Section 6.

While data minimization is the best strategy for protecting privacy, there are many occasions in daily life when individuals simply have to reveal personal data, or when users want to present themselves by disseminating personal information (especially on social network sites). In these cases, the privacy of the individuals concerned still needs to be protected by adhering to other relevant legal privacy requirements). The second class of PETs therefore comprises technologies that enforce legal privacy requirements, such as informed consent, transparency, right to data subject access, purpose specification, and purpose binding and security, in order to safeguard the lawful processing of personal data. In this chapter, so-called transparency-enhancing technologies will be discussed, which are PETs that enforce or promote informed consent and transparency. Besides, we will refer to privacy models and privacy authorization languages for enforcing the principle of purpose binding.

The third class of PETs comprises technologies that combine PETs of the first and second class. An example is provided by privacy-enhancing identity management technologies such as the ones that have been developed within the EU FP6 project PRIME (Privacy and Identity Management for Europe) [14]. The PRIME architecture supports strong privacy by default by anonymizing the underlying communication and achieving data minimization on the application level by the use of anonymous credential protocols. Besides privacy presentation and

negotiation tools, privacy authorization language for enforcing negotiated policies and tools allowing users to "track" and access their data that they released to remote services sides ensure the technical enforcement of all privacy requirements mentioned in the section above.

4. TRADITIONAL PRIVACY GOALS OF PETS

In this section, privacy goals for achieving data minimization are defined, which we call traditional privacy goals because early PETs that were developed already in the 1980s followed these goals. Data minimization as an abstract strategy describes the avoidance of unnecessary or unwanted data disclosures. The most fundamental information that can be disclosed about an individual is who he is, that is, an identifier, or which observable events he is related to. If this information can be kept secret, the individual remains anonymous. Pfitzmann and Hansen, who pioneered the technical privacy research terminology, define anonymity as follows: Anonymity of a subject means that the subject is not identifiable within a set of subjects, the anonymity set [14].

By choosing the term *subject*, Pfitzmann and Hansen aim to define the term *anonymity* as generally as possible. The subject can be any entity defined by facts (names or identifiers, or causing observable events, such as by sending messages). If an adversary cannot narrow down the sender of a specific message to less than two possible senders, the actual sender of the message remains anonymous. The two or more possible senders in question form the anonymity set. The anonymity set, and particularly its size, will be the first privacy metrics discussed in Section 5, Privacy Metrics.

An adversary that discovers the relation between a fact or an event and a subject identifies the subject. Relations cannot only exist between facts or events and subjects, but may exist between facts, actions, and subjects. An adversary may, for instance, discover that two messages have been sent by the same subject, without knowing this subject. The two messages would be part of the equivalence relation [15] that is formed by all messages that have been sent by the same subject. Knowing this equivalence relation (and maybe even others) helps the adversary to identify the subject. Pfitzmann and Hansen define the inability of the adversary to discover these equivalence relations as unlinkability.

Unlinkability of two or more items of interest (IOIs (subjects, messages, actions, . . .)) from an attacker's perspective means that within the system (comprising these and possibly other items), the attacker cannot sufficiently distinguish whether these IOIs are related or not [14].

A special type of unlinkability is the unlinkability of a sender and recipient of a message (or so-called relationship anonymity), which means that the relation of who is communicating with whom is kept secret. Data minimization can also be implemented through obfuscating the presence of facts and events. The idea is that adversaries who are unable to detect the presence of facts or events cannot link them to subjects. Pfitzmann and Hansen define this privacy goal as undetectability.

Undetectability of an item of interest (IOI) from an attacker's perspective means that the attacker cannot sufficiently distinguish whether it exists or not [14].

The strongest privacy goal in data minimization is unobservability, which combines undetectability and anonymity: Unobservability of an item of interest (IOI) means:

- undetectability of the IOI against all subjects uninvolved in it and
- anonymity of the subject(s) involved in the IOI even against the other subject(s) involved in that IOI [14].

The third and last way to implement data minimization, apart from obfuscating the facts, the events (undetectability, unobservability), or the relation between them and the subjects (unlinkability), is the use of pseudonyms in the place of subjects. Pseudonyms may be random numbers, email addresses, or (cryptographic) certificates. In order to minimize the disclosed information, pseudonyms must not be linkable to the subject. The corresponding privacy goal is pseudonymity: Pseudonymity is the use of pseudonyms as identifiers [14].

Pseudonymity is related to anonymity, as both concepts aim at protecting the real identity of a subject. The use of pseudonyms, however, allows maintaining a reference to the subject's real identity (for accountability purposes [16]). A trusted third party could, for instance, reveal the real identities of misbehaving pseudonymous users. Pseudonymity also enables a user to link certain actions under one pseudonym. For example, a user could reuse the same pseudonym in an online auction system (such as eBay) for building up a reputation.

The degree of anonymity protection provided by pseudonyms depends on the amount of personal data of the pseudonym holder that can be linked to the pseudonym, and on how often the pseudonym is used in various contexts/for various transactions. The best privacy protection can be achieved if for each transaction a new so-called transaction pseudonym is used that is unlinkable to any other transaction pseudonyms and at least initially unlinkable to any other personal data items of its holder (see also [14]).

5. PRIVACY METRICS

Privacy metrics aim to quantify the effectiveness of schemes or technologies with regard to the privacy goals

defined in the previous section. A simple metrics for measuring anonymity is the anonymity set [14]. The anonymity set comprises all subjects that may have caused an event that is observed by the adversary. The subjects in the set cover up for each other against the adversary. The adversary can thus not hold a single subject responsible for the observed event as long as the set size of the anonymity set is greater than one. Greater set sizes are useful for protecting against (stronger) adversaries that would accept false positives up to a certain threshold among the subjects that are held responsible. In this case, the set size has to exceed such a threshold.

The anonymity set size is also related to the metrics in k-anonymity [17]. K-anonymity is defined as a property or a requirement for databases that must not leak sensitive private information. This concept was also applied as an anonymity metrics in location-based services [18] and in VoIP [19,20]. The underlying assumption is that database tables store two kinds of attributes. The first kind is identifying information, and the second is identifying sensitive information. The claim is that the database table is anonymous if every search for identifying information results in a group of at least k candidate records. The k in k-anonymity is thus the privacy parameter that determines the minimum group size. Groups of candidate records form anonymity sets of identifiers in the database table.

The k-anonymity as a privacy property and k as a metrics are not undisputed. In particular, the fact that k-anonymity only depends on the identifying information in the database table—that is, it is independent of the sensitive information—leads to remaining privacy risks [21]. A simple attack building on the k-anonymity's blindness for sensitive information is described in [22]. The trick is to search for candidate groups where the sensitive attribute has a constant value for all candidates. The sensitive attribute value is immediately disclosed for all records in the candidate group; thus, privacy is breached. A solution to these risks is a new privacy property, l-diversity, with the privacy parameter l. The claim of l-diversity is that a database table is anonymous if the diversity of sensitive attribute values is at least l ($>$ 1) in every candidate group. In some cases, l-diversification would not sufficiently protect from attribute disclosure or would be too difficult to establish. A third property, t-closeness [23], is solving this problem. T-closeness restricts the distribution of sensitive information within a candidate group. The claim is that a database table is anonymous if the distribution of sensitive information within each candidate group differs from the table's distribution at most up to a threshold t.

All these privacy metrics with the exception of the anonymity set are tailored to static database tables. Changes in the data set are possible, but the privacy properties have to be reestablished afterward. T-closeness as one of the latest developed properties in this category is a close relative to information-theoretic privacy metrics. Information-theoretic metrics measure the information that an adversary learns by observing an event or a system, for example, all observable events in a communication system. The information always depends on the knowledge the adversary had before his observation, the a-priori knowledge. Knowledge is expressed as a probability distribution over the events. For a discrete set of events $X = \{x_1, x_2, \ldots, x_n\}$ and the probability mass function $\Pr: X \rightarrow [0, 1]$, Shannon [24] defines the self-information of x_i, $1 \leq i \leq n$, as

$$I(x_i) = -\log_2 \Pr(x_i)$$

The self-information $I(x_i)$ is what an adversary learns when he observes the event x_i with his a-priori knowledge about all possible events encoded in the probability mass function Pr. The self-information takes the minimal value zero for $\Pr(x_i) = 1$; that is, the adversary will learn minimal information from observing x_i, if he is a-priori certain that x_i will be observed. The self-information approaches infinity for $\Pr(x_i) \rightarrow 0$; that is, the more information the adversary learns, the less likely the observed events are. The expected self-information of a system with the events X is the entropy of the system. Shannon defines the entropy as

$$H(X) = \sum_{x_i \in X} \Pr(x_i) \cdot I(x_i)$$

The entropy is maximal when the distribution of all events is uniform; that is, $\Pr(x_i) = \frac{1}{n}$ for all $1 \leq i \leq n$. The maximal entropy is thus

$$H_{\max} = -\log_2 \frac{1}{n} = \log_2 n$$

The entropy is minimal when one event x_i is perfectly certain; that is, $\Pr(x_i) = 1$ and $\Pr(x_j) = 0$ for all $x_j \in X$ and $x_j \neq x_i$.

The "degree of anonymity" is the entropy of the communication system in question [25,26]. This degree of anonymity measures the anonymity of the message's sender within the communication system. When the adversary learns the actual sender of the message, he will learn the self-information $I(x_i)$ where each $x_i \in X$ encodes the fact that one specific subject is the sender of the message. The probability distribution Pr encodes the a-priori knowledge of the adversary about the sender. A uniform distribution (maximal entropy) indicates minimal a-priori knowledge (maximal sender anonymity). Absolute certainty, on the other hand (minimal entropy), indicates perfect a-priori knowledge (minimal sender anonymity). The degree of anonymity can be used to compare communication systems with different features (numbers of subjects)

when normalized [25] with max entropy H_{max} and otherwise without normalization [26].

The same entropy-based metrics can be applied to measure the anonymity provided by facts about a subject [27]. The adversary's a-priori knowledge, encoded in the probability mass function Pr, comprises how well a feature vector with facts about a subject fits to each subject $x_i \in X$. The adversary learns the self-information $I(x_i)$ when learning that the feature vector applies to the subject x_i. The entropy $H(X)$ can be seen as the confusion of the adversary before he learns the subject that the feature vector is applying to.

The entropy can be used to calculate the expected anonymity set size, which is $2^{H(X)}$. The expected anonymity set size is equal to the anonymity set size, if Pr corresponds to the uniform distribution (if the message [25,26] or feature vector [27] is not more or less linkable to one subject than to any other subject in X). The anonymity set size can be seen as an overestimation of the expected anonymity set size, if Pr does not correspond to the uniform distribution; that is, some subjects are more linkable than others in the anonymity set. In this case, the expected anonymity set size or the degree of anonymity is the more accurate metrics.

Metrics that are based on entropy have the disadvantage that the a-priori knowledge Pr of the adversary has to be known when evaluating the metrics. When this a-priori knowledge can be derived from publicly available observations (message routing data in a network [25,26]), the metrics are easy to apply. If the Pr depends on personal information which is not available to nonadversaries [27], the metrics are hard to evaluate without additional tools being effective (legal transparency tools).

6. DATA MINIMIZATION TECHNOLOGIES

In this section, we will present the most relevant PETs for minimizing data on both communication and application levels. It is important to note that applications (such as eCommerce applications) can only be designed and used anonymously if their users cannot be identified on a communication level (via their IP addresses). Hence anonymous communication is a prerequisite for achieving anonymity, more generally or data minimization, on the application level.

Anonymous Communication

Already in 1981, David Chaum presented the Mix net protocol for anonymous communication, which has become the fundamental concept for many practical anonymous communication technologies that have been broadly used for many years. In this section, we will provide an overview to anonymous communication technologies that we think are most relevant from a practical and scientific point of view.

DC Network

David Chaum's DC (Dining Cryptographer) network protocol [28] is an anonymous communication protocol, which, even though it cannot be easily used in practice, is still very interesting from a scientific perspective. It provides unconditional sender anonymity, recipient anonymity, and unobservability, even if we assume a global adversary who can observe all communication in the network. Hence, it can guarantee the strongest anonymity properties of all known anonymous communication protocols. DC nets are based on binary superposed sending. Before any message can be sent, each participant in the network (user station) has to exchange via a secure channel a random bit stream with at least one other user station. These random bit streams serve as secret keys and are at least as long as the messages to be sent. For each single sending step (round), every user station adds modulo 2 (superposes), all the key bits it shares and its message bit, if there is one. Stations that do not wish to transmit messages send zeros by outputting the sums of their key bits (without any inversions). The sums are sent over the net and added up modulo 2. The result, which is broadcast to all user stations, is the sum of all sent message bits because every key bit was added twice (see Figure 43.1). If exactly one participant transmits a

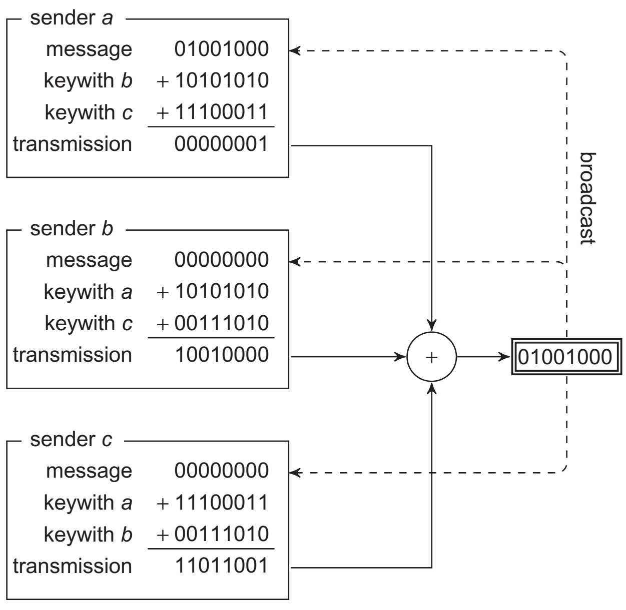

FIGURE 43.1 A DC network with three users. Sender a sends a message, but from observing the communication in the network alone, the adversary cannot tell whether it was sent by a, b, or c (and not even if a meaningful message was sent at all).

message, the message is successfully broadcast as the result of the global sum to each participant. Collisions are easily detected (as the message sent by a user and the one that is broadcast back to him will be different) and have to be resolved, for example, by retransmitting the message after a random number of rounds.

In theory, superposed sending provides, in the information-theoretic sense, perfect (unconditional) sender anonymity and unobservability, as the fact that someone is sending a meaningful message (and not only zeros) is hidden by a one-time pad encryption. From a metrics perspective, all senders in the DC network form the anonymity set. No user is more likely to be the sender of the message than any other user for an outside adversary. Perfect recipient anonymity can be achieved by reliable broadcasting. However, the DC network and the one-time pad share the same practical shortcomings which have prevented them from being broadly used: the security of DC networks depends on the perfect randomness of keys and the secure distribution of keys. Moreover, each key is to be used only once, and the keys need to be perfectly unavailable to the adversary (the adversary may not get hold of the keys before or after the message has been sent).

Mix Nets

Mix nets [12] are more practical than DC networks, but do not provide security against adversaries with unlimited resources. Nevertheless, most anonymity networks (Mixmaster, Tor, Onion Routing, and AN.ON) build on the mix net concept. A mix is a relay or proxy server that performs four steps to hide the relation between incoming and outgoing messages (see Figure 43.2):

1. Duplicates (replayed messages) are discarded. Without this functionality, an adversary could launch a replay attack by sending two identical messages to be forwarded as two identical output messages by the mix. The adversary could thus link these messages and therefore "bridge over" the mix.
2. All messages are (randomly) delayed (by temporarily storing them in a buffer). Without this functionality (if messages were immediately forwarded), the anonymity set for one message would be reduced to one sender (no anonymity at all).

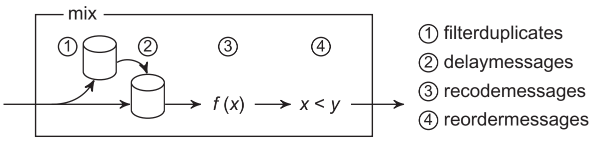

FIGURE 43.2 Processing steps within a mix.

3. All messages are recoded. This is usually done by cryptography. Without this functionality, the adversary could link the input with the output messages by comparing the contents of the messages.
4. The sending sequence of delayed messages is determined independently of the receiving sequence. Without the delay and reordering of messages, an adversary could link the input to the output messages by a time correlation attack (he could be sure that the first message is the first message out).
5. Mixes can be used to achieve unlinkability of sender and recipient, sender anonymity as well as recipient anonymity. For achieving the latter two properties, different recoding functions are used. For providing sender anonymity, asymmetric cryptography is used. The mix user (or more precisely his machine) encrypts the message m with the public key e_R of the recipient and achieves $enc_{e_R}(m)$. He then encrypts $enc_{e_R}(m)$ together with the address of the recipient and a nonce with public key e_1 of the mix and sends the resulting message $enc_{e_1}(r_1, A_R, enc_{e_R}(m))$ to the mix. Adding the nonce is necessary to achieve nondeterministic encryption, which prevents an adversary from monitoring the output message $enc_{e_R}(m)$ and address A_R of the recipient, and then simply encrypt both values with the public key of the mix and compare it with the messages sent to the mix. Moreover, it prevents the mix from discarding one of two messages when identical contents are intended to be sent. The mix decrypts the message with its private key, discards the nonce, and sends $enc_{e_R}(m)$ to the address A_R of the recipient.
6. Using a single mix can only provide anonymity if it is fully trustworthy and cannot be compromised. For improving security, several mixes can be used in a chain or a "cascade." Let us assume that the sender (or more precisely his machine) chooses a chain of n mixes with addresses A_i and public keys e_i, $i = 1\ldots n$. The sender will first add layers of encryptions using the public keys of the mixes in the path in reverse order. Each layer includes the message to be forwarded by the mix, the address to which the message should be sent (next mix in the chain or the final recipient), plus a nonce to be discarded. The resulting message $enc_{e_1}(r_1, A_2, enc_{e_2}(\ldots enc_{e_n}(r_n, A_R, enc_{e_R}(m))\ldots))$ is sent to the first mix (with the address A_1). Each mix on the path decrypts the message with its privacy key and thereby gets a nonce that is discarded as well as an encrypted message and address to which it sends this message. The last mix in the path finally sends $enc_{e_R}(m)$ to the recipient. Unlinkability of sender and recipient can in principle also be provided in the presence of an adversary who monitors all communication lines, as long as the crypto operations cannot be broken and one mix in the path is trustworthy, that is, one

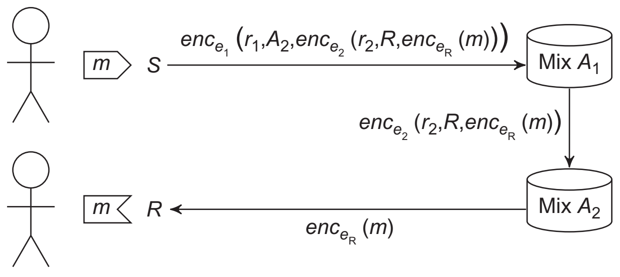

FIGURE 43.3 Sender anonymity with two mixes.

mix that is not controlled by the adversary. Figure 43.3 illustrates how sender anonymity can be achieved with a path consisting of two mixes.

For achieving recipient anonymity, symmetric cryptography is used as arecoding function.[5] The recipient first chooses a sequence of n mixes with addresses A_i and public keys e_i, $i = 1 \ldots n$, a sequence of m symmetric encryption keys $j = 0 \ldots n$, and a label $L_R$and creates an anonymous return address $R_S = (k_0, A_1, R_1)$, which contains a symmetric key k_0, the address of the first mix A_1 in the chain, and another anonymous return address R_1, which is calculated according to the following scheme:

$R_j = enc_{e_i}(k_j, A_{j+1}, R_{j+1})$ for$j = 1 \ldots n$, where A_{n+1} is the address of the recipient and $R_{n+1} = L_R$.

The recipient makes the anonymous return address available to the sender, who uses key k_0 to encrypt his message m. The encrypted message $ENC_{k_0}\{m\}$ is then sent along with the return address R_1 to the first mix A_1. The first mix decrypts $R_1 = enc_{e_1}(k_1, A_2, R_2)$, encrypts $ENC_{k_0}\{m\}$ with the symmetric key k_1, and sends the encrypted message $ENC_{k_1}\{ENC_{k_0}\{m\}\}$ along with R_2 to the next mix with the address A_2. This is repeated for all mixes along the path. The last mix in the path finally forwards $ENC_{k_n}\{\ldots ENC_{k_1}\{ENC_{k_0}\{m\}\}\ldots\}$ and L_R to the recipient. The label L_R of the return address indicates to the recipient which sequence of symmetric keys he has to use to decrypt the message.

The two schemes above provide either sender or recipient anonymity. By combining both schemes, it is possible for two communication partners to communicate anonymously in both directions. Suppose that Alice anonymously sends a message including an anonymous return address to a discussion forum. Bob can then anonymously send his reply via a self-chosen sequence of mixes to the first mix used in the anonymous return address. If Bob's message also contains an anonymous return address, Alice can reply as well in the same manner. Thus, Alice and Bob can communicate without knowing each other's identities.

The mix net protocol was invented by Chaum in 1981 for high-latency communication, such as email communication. In the mid-1990s, when interactive Internet services became broadly used, low-latency anonymous communication protocols were developed. The most broadly used low-latency protocols AN.ON and Onion Routing/Tor, which are based on the mix net concept, will be briefly presented in the next sections.

AN.ON

AN.ON [29] is an anonymity service that was developed and operated since the late 1990s at the Technical University of Dresden. Because it aims at providing a network of mixes for low-latency traffic routing, symmetric cryptography is replacing asymmetric cryptography where possible (asymmetric cryptography is only used to exchange symmetric session keys between mixes and users). Moreover, low latency requires that message delays are reduced, and in fact, AN.ON mixes implement practically no message delay. The downside of reducing delays is that the size of the message buffer in the mixes and thus the anonymity set decrease. In order to increase the size of anonymity sets, AN.ON provides standard routes through the mix network, the so-called mix cascades. A mix cascade typically contains a sequence of two or three mixes, and every message sent to the cascade runs through the mixes in the same order as any other message sent to the same cascade. Predefined and stable mix cascades have a number of advantages over dynamic routing:

1. Mixes can be audited and certified with regard to their performance, their geographical position, the legislation in which they operate, and the operator (the company or the governmental institution operating the mix infrastructure).
2. Cascades can be designed to cross different nations, different legislations, and different operators in order to enjoy the protection of the most liberal regulation; they can also be designed to provide a certain performance.
3. Security measures focus on a small number of mixes while the costs can be distributed to a large number of users.

Disadvantages of implementing mix cascades include:

1. Each mix is a possible bottleneck and thus needs to provide a stable and high-bandwidth installation, as one mix going offline stops all cascades in which it was involved.

5. In the following, we will use capital letters and curly brackets for the symmetric encryption function ENC.

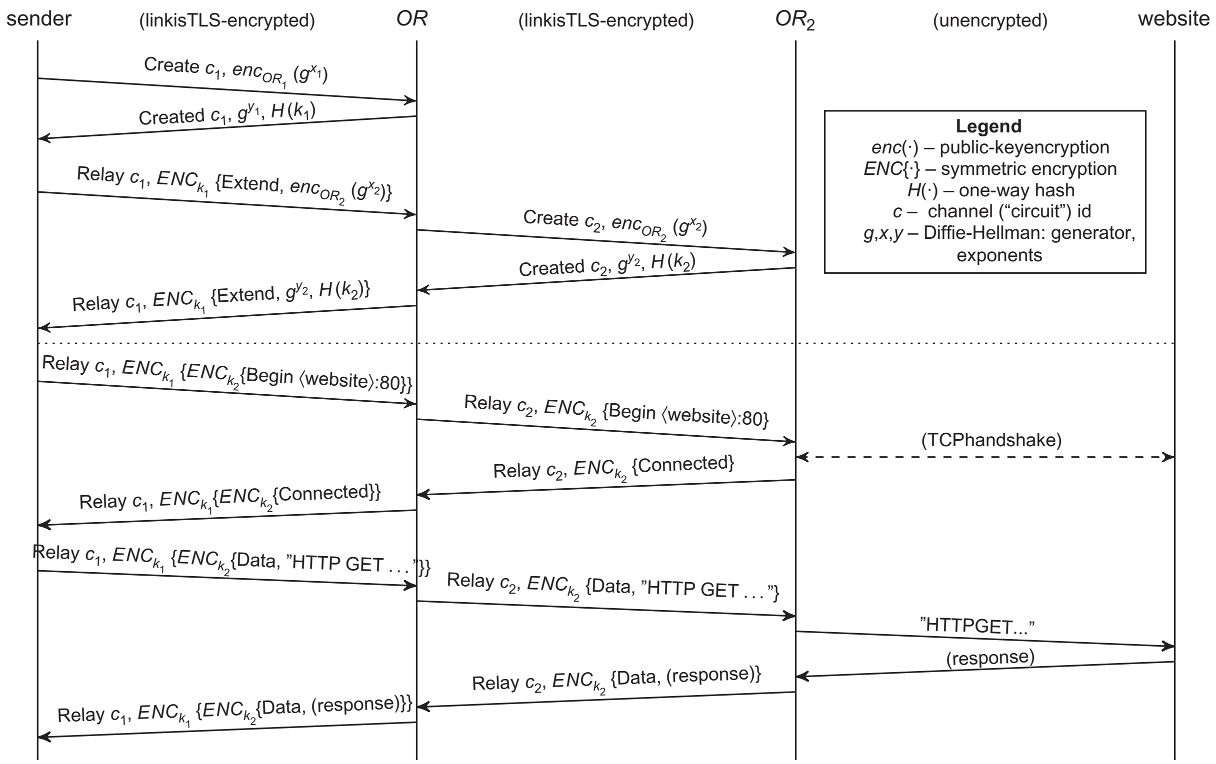

FIGURE 43.4 The Tor key negotiation and a simple Web site request [31].

2. Setting up and operating mixes is expensive due to the considerable organizational overhead for establishing mix cascades and due to the high performance requirements.

Onion Routing/Tor

Onion Routing [30] is a low-latency, mix-based routing protocol developed in the 1990s at the Naval Research Laboratory. It provides anonymous socket connections by means of proxy servers. Onion Routing uses the mix net concept of layers of public key encryption (the so-called onion) to build up an anonymous bidirectional virtual circuit between communication partners. The initiator's proxy (for the service being requested) constructs a "forward onion," which encapsulates a series of routing nodes ("mixes") forming a path to the responder, and sends it with a create command to the first node. Each layer of the onion is encrypted with the public key of each node on the path and contains symmetric crypto function/key pairs as a payload. After sending the onion, the anonymous path is established and the initiator's proxy sends data through this anonymous connection. The symmetric function/key pairs are applied by each node on the path to crypt data that will be sent along the virtual circuit. All information (onions, data, and network control) are sent through the Onion Routing network in uniform-sized cells. All cells arriving at an onion router within a fixed time interval are mixed together to reduce correlation by network insiders. Reply onions, which correspond to untraceable return addresses, allow for a responder to send back anonymously a reply after its original circuit is broken.

Since individual routing nodes in each circuit only know the identities of adjacent nodes, and since the nodes further encrypt multiplexed virtual circuits, traffic analysis is made difficult. However, if the first node behind the initiator's proxy and the last node of the circuit cooperate, they will be able to determine the source and recipient of communication through the number of cells sent over this circuit or through the duration for which the virtual circuit was used.

Tor [31], the second generation of Onion Routing, has added several improvements. In particular, it provides forward secrecy. Once the session keys are deleted they cannot be obtained any longer. Even if all communication has been wiretapped, the long-term secret keys of the onion routers ("mixes") become compromised. Therefore, instead of using hybrid encryption for distributing symmetric session keys, the Diffie-Hellman key negotiation protocol is used, which provides forward secrecy. The key negotiation and a simple communication via two onion routers are outlined in Figure 43.4. The symmetric session key shared by the user with the first onion router

OR_1 is negotiated by means of a Diffie-Hellman handshake. The first half of the handshake g^{x_1} is encrypted with the public key of OR_1 (to prevent man-in-the-middle attacks), and $enc_{OR_1}(g^{x_1})$ is then sent to OR_1. The onion router replies with the second half of the handshake; that is, g^{y_1} and a hash over the negotiated session key $k_1 = g^{x_1 y_1}$. Any further communication between the sender and OR_1 will be crypted with this negotiated symmetric session key. In order to extend the path from the sender over OR_1 to a second onion router OR_2, the sender transmits $ENC_{k_1}\{OR_2, enc_{OR_2}(g^{x_2})\}$ to OR_1. The first onion router decrypts the symmetric encryption and forwards the encrypted first half of a new Diffie-Hellman handshake $enc_{OR_2}(g^{x_2})$ to OR_2. The second onion router replies with the second half of the handshake g^{y_2} and the hash over the session key $k_2 = g^{x_2 y_2}$. The reply $ENC_{k_1}\{g^{y_2}, hash(k_2)\}$ is forwarded by OR_1 back to the sender. Only the sender and OR_1 are now in possession of k_1 and only the sender and OR_2 are now in possession of k_2. The communication between sender and OR_2 can now be crypted with k_2. Once a circuit has been established, the symmetric encryption with the negotiated session keys is applied by each node on the path to crypt data that will be sent along the circuit. Advantages of Tor over AN.ON are as follows:

1. Tor provides forward secrecy.
2. It is easy to set up new onion routers ("mixes"), which are run by many volunteers all over the world.
3. There are lower performance requirements for each "mix."
4. Each mix is a possible bottleneck, however, in Tor, "mixes" that do not perform can be excluded from the dynamic routing.

Disadvantages include:

1. Anyone can set up "mixes" independent of their performance, that is, bandwidth, latency, security.
2. There is no audit or certification, thus a lack of reliable data about legislation and operator.
3. Bridging the "mixes" and thus breaching anonymity by controlling the entry node and the exit node is easier for adversaries, since they can easily set up their own new nodes. In particular, an adversary can easily try to attract user traffic by establishing a few well-performing exit nodes and a lot of stable intermediate mix nodes that eventually become entry nodes [32].

Data Minimization at Application Level

Even if the communication channel is anonymized, users can still reveal personal and identifying data on the application level; often users have to reveal more personal data than needed. Hence, data minimization techniques are also needed on the application level. Many such data minimization techniques are based on cryptographic protocols (see also [33] for an overview). The classical types of privacy-protecting cryptography that have already been applied for decades are of course encryption schemes themselves. However, there are a number of more recent crypto schemes for protecting data and authenticating information, which are variations or extensions of basic crypto schemes they have "surprising properties" that in many cases can offer better data minimization properties [33]. In this chapter, some of the most relevant examples of mainly cryptographic mechanisms for protecting privacy at application level will be given.

Blind Signatures and Anonymous eCash

Blind signatures are an extension of digital signatures and provide privacy by allowing someone to obtain a signature from a signer on a document without the signer seeing the actual content of the "blinded" document he is signing. Hence, if the signer is later presented with the signed "unblinded" document, he cannot relate it with the signing session and with the person on behalf of whom he has signed the document. Blind signatures were invented by David Chaum as a basic building block for anonymous eCash (see below). They can also be used to achieve anonymity of other applications, such as eVoting, and also serve as a basic building block for other privacy crypto protocols, such as anonymous credentials (see below).

David Chaum et al. have invented protocols based on blind signatures [10,34,35], which allow electronic money to flow perfectly tracelessly from the bank through consumer and merchant before returning to the bank. Chaum's cryptographic "online" payment protocol based on blind signatures can be summarized as follows (see also Figure 43.5).

Let (e, n) be the bank's private key indicating a certain value of a signature under this key (in this example: one dollar) and (d, n) the bank's public key.[6] f is a suitable one-way function. Electronic money has the form $(x, f(x)^d \pmod n)$, where the one-way function is needed to prevent forgery of electronic money (see also [36] for more explanations).

1. The customer Alice (his computer) first generates a bank note number x (of at least 100 digits) at random and (in essence) multiplies it with a blinding factor r, which he has also chosen at random: $B = r^e \cdot f(x) \pmod n$. He then signs the blinded bank note number with his private key and sends it to the bank.
2. The bank verifies and removes Alice's signature. Then, it signs the blinded note (and thereby creates

6. Using the RSA encryption scheme.

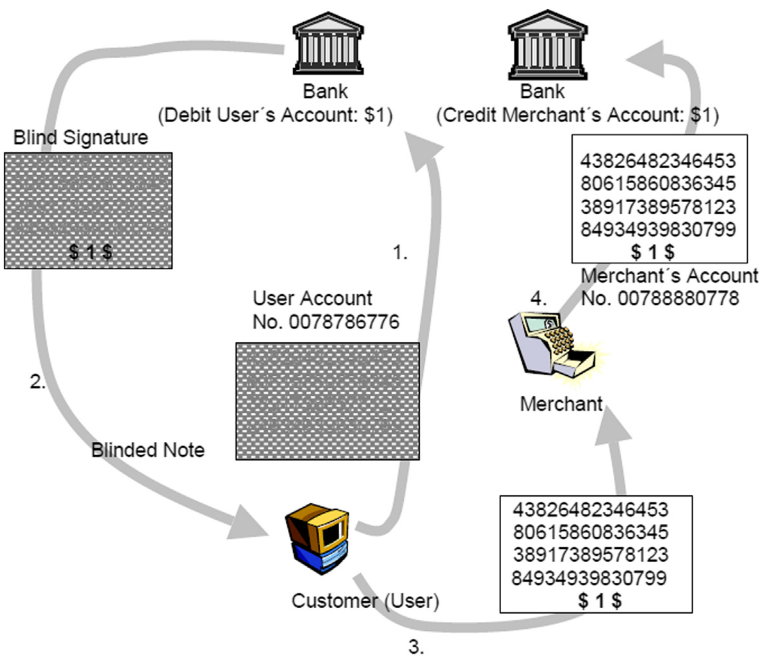

FIGURE 43.5 The flow of eCash's untraceable electronic money [35].

the blinded signature) with its "worth one dollar" signature:
$B^d \pmod n = (r^e \cdot f(x))^a \pmod n = r \cdot f(x)^d \pmod n$.
The bank then withdraws one dollar from his account and returns the note with the blind signature.

3. Alice divides out the blinding factor and thereby extracts: $C = \frac{B^d}{r} (\bmod n) = f(x)^d \pmod n$ from B. For paying the online merchant Bob one dollar, Alice sends him the pair $(x, f(x)^d \ (\mathrm{mod} n))$.
4. Bob verifies the bank's signature and immediately contacts the bank to verify that the note has not already been spent.
5. The bank verifies its signature, checks the note against a list of those notes already spent, and credits Bob's account by one dollar.

The blind signature scheme provides (unconditional) anonymity of the electronic money: Even if the bank and the merchant cooperate, they cannot determine who spent the notes. Since the bank does not know the blinding factors, it cannot correlate the note it was signing blindly for Alice with the note that was spent. (However, Alice's identity is only protected if he also uses an anonymized communication channel and if he does not personally reveal identifying information, such as a personal delivery address).

In addition to the online eCash protocol version, where the bank needs to be constantly online for checking whether notes have already been spent, in [28] a protocol for offline electronic money is presented by Chaum et al. With the offline protocol, a user remains unconditionally anonymous as long as he spends each bank note only once. If, however, a note is spent twice, the bank will get enough information to identify the spender's account. Disappointingly, there has been a lack of adoption of anonymous eCash (attempts of commercial deployment of Chaum's schemes failed in the late 1990s), and today, there are still no widely deployed anonymous electronic payment services.

Zero-Knowledge Proofs

A zero-knowledge proof is defined as an interactive proof in which a prover can prove to a verifier that a statement is true without revealing anything else than the veracity of the statement. Zero-knowledge proofs were first presented in 1985 by Goldwasser et al. [37]. A zero-knowledge proof must fulfill the following three properties:

- *Completeness:* If the statement is true, the honest verifier will be convinced of this fact by an honest prover.
- *Soundness:* If the statement is false, no cheating prover can convince the honest verifier that it is true, except with some very small probability.
- *Zero-knowledge:* If the statement is true, no cheating verifier learns anything other than this fact.

Zero-knowledge proofs are building blocks for data-minimizing technologies, such as anonymous credential systems. The anonymous credential protocol IdeMix is, for example, based on proofs of knowledge, in which a prover proves that he knows a secret value or that he is

able to solve some number theoretic problem, which would contradict the assumption that the problem cannot be solved by a polynomially bounded Turing machine.

Anonymous Credentials

A traditional credential (often also called certificate or attribute certificate) is a set of personal attributes, such as birth date, name or personal number, signed (and thereby certified) by the certifying party (the so-called issuer), and bound to its owner by cryptographic means (by requiring the user's secret key to use the credential). In terms of privacy, the use of (traditional or anonymous) credentials is better than the direct request to the certifying party, as this prevents the certifying party from profiling the user. Traditional credentials require, however, that all attributes are disclosed together if the user wants to prove certain properties, so that the verifier can check the issuer's signature. This makes different uses of the same credential linkable to each other. Moreover, the verifier and issuer can link the different uses of the user's credential to the issuing of the credential.

Anonymous credentials (also called private certificates) were first introduced by Chaum [10] and later enhanced by Brands [38] and by Camenisch and Lysyanskaya [39] and have stronger privacy properties than traditional credentials. Microsoft's U-Prove technology based on Brands's protocols and IBM's IdeMix technology based on the credential protocols by Camenisch et al. are currently the practically most relevant anonymous credential technologies.

Anonymous credentials allow the user to essentially "transform" the certificate into a new one that contains only a subset of attributes of the original certificate (it allows proving only a subset of its attributes to a verifier (*selective disclosure property*)). Instead of revealing the exact value of an attribute, anonymous credential systems also enable the user in the transformation to apply any mathematical function to the (original) attribute value, allowing him to prove only attribute properties without revealing the attribute itself. Besides, with the IdeMix protocol by Camenisch et al., the issuer's signature is also transformed in such a way that the signature in the new certificate cannot be linked to the original signature of the issuer [33]. Hence, different credential uses cannot be linked by the verifier and/or issuer (*unlinkability property*). Cryptographically speaking, with IdeMix, the user is basically using a zero-knowledge proof to convince the verifier of possessing a signature generated by the issuer on a statement containing the subset of attributes.

Figure 43.6 provides a scenario illustrating how data minimization can be achieved in an identity management online transaction: First, user Alice obtains an anonymous driving license credential issued by the Swedish Road authority (the so-called identity provider), with personal attributes typically stored in the license, including her birth date. Later, she would like to purchase a video from an online shop (the so-called relying party, which is also the verifier in this scenario), which is only permitted for adults. After sending a service request, the online shop will answer her with a data request for a proof that she is older than 18. Alice can now take advantage of the selective disclosure feature of the anonymous credential protocol to prove with her credential just the fact that she is older than 18 without revealing her birth date or any other attributes of her credential. If Alice later wants to purchase another video that is only permitted for adults at the same video online shop, she can use the same anonymous credential for a proof that she is over 18. If the IdeMix protocol is used, the video shop is unable to recognize that the two proofs are based on the same credential. Hence, the two rental transactions cannot be linked to the same person.

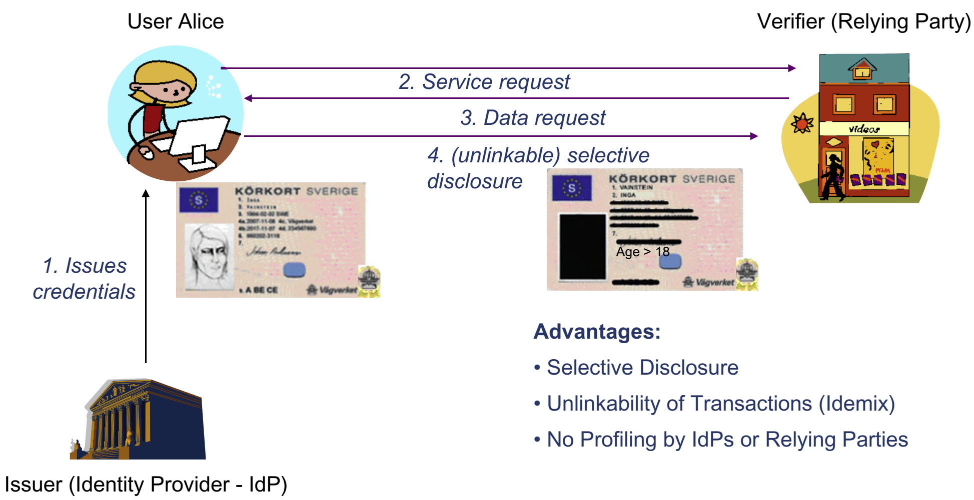

FIGURE 43.6 Example for achieving data minimization for an online transaction by the use of anonymous credentials.

Private Information Retrieval

Private Information Retrieval (PIR) allows a user to retrieve an item (record) from a database server without revealing which item he is interested in; that is, the privacy of the item of interest is provided. A typical application example is a patent database from which inventors would like to retrieve information without revealing their interests. A trivial approach would be to simply download the entire database and to make a local selection, which would, however, be too costly bandwidth-wise. In [40], one of the first PIR solutions was introduced, which requires the existence of $t+1$ noncooperating identical database servers (with n records each). To each server, one n-bit query vector (out of a set of $t+1$ query vectors) is sent via an encrypted channel, where each bit represents one record of the queried database: If the bit is one, then the record is selected; otherwise not. The user creates t of the query vectors randomly. The remaining $t+1$st vector is calculated by XOR-ing (superposing) all random vectors and flipping the bit representing the record of interest. One of the query vectors is sent to each database. All selected records are superposed (XOR-ed). The result is exactly the requested database item. If each of the bits in the t random query vectors is set to 1 with a probability of 0.5, then an adversary who has access to at most t of the requests or responses associated with the query vectors will gain no information about the database item that the user is retrieving.

A disadvantage of a multi-database solution is, however, that several identical databases must be obtained. Especially updates are complex, as changes should take place simultaneously. Besides information-theoretic PIR schemes with database replication, several single-database (computational) PIR schemes have been subsequently developed and advanced (see, for instance, [41,42] for surveys and references). Oblivious transfer [42] is private information retrieval, where additionally the user may not learn any item other than the one that he requested.

7. TRANSPARENCY-ENHANCING TOOLS

As we elaborated above, transparency is a basic legal principle. It is also an important social trust factor, as trust in an application can be enhanced if procedures are clear, transparen,t and reversible, so that users feel they are in control [43]. Transparency-enhancing technologies provide tools to the end users or their proxies acting on behalf of the user's interests (such as data protection commissioners), for making personal data processing more transparent to them.

Classification

Transparency-enhancing tools (TETs) for privacy purposes can be classified into the following categories (see also [44]):

1. TETs that provide information about the intended data collection and processing to the data subject, in order to enhance the data subject's privacy;
2. TETs that provide the data subject with an overview of what personal data have been disclosed to which data controller under which policies;
3. TETs that provide the data subject, or his proxy, online access to his personal data, to information on how his data have been processed and whether this was in line with privacy laws and/or negotiated policies, and/or to the logic of data processing in order to enhance the data subject's privacy;
4. TETs that provide "counter-profiling" capabilities to the data subject, helping him to "guess" how his data match relevant group profiles, which may affect his future opportunities or risks;

TETs of the first and last categories are also called *ex-ante* TETs, as they provide transparency of any intended data processing to the data subjects before they are releasing any personal data. TETs of the second and third categories provide transparency in regard to the processing of personal data, which the user has already disclosed, and are therefore called *ex-post* TETs.

Ex-ante Transparency-Enhancing Tools

Examples of ex-ante TETs are privacy policy languages tools and Human Computer Interaction (HCI) components that make privacy policies of services sides more transparent, such as the Platform for Privacy Preferences (P3P) language [45] and P3P user agents, such as the privacy bird.[7] P3P enables Web sites to express their privacy policy (basically stating what data are requested by whom, for what purposes, and how long the data will be retained) in a standard (machine-readable XML) format that can be retrieved automatically and interpreted easily by user agents and matched with the user's privacy preferences. Thus, P3P user agents enable users to be better informed of a Web site's data-handling practices (in both machine- and human-readable formats).

Recently developed visualization techniques for displaying P3P-based privacy policies are based on the metaphor of a "Nutrition Label," assuming that people already understand other nutrition, warning, and energy labeling, which consequently can also allow users to find and digest policy-related information with a proposed privacy

7. http://www.privacybird.org.

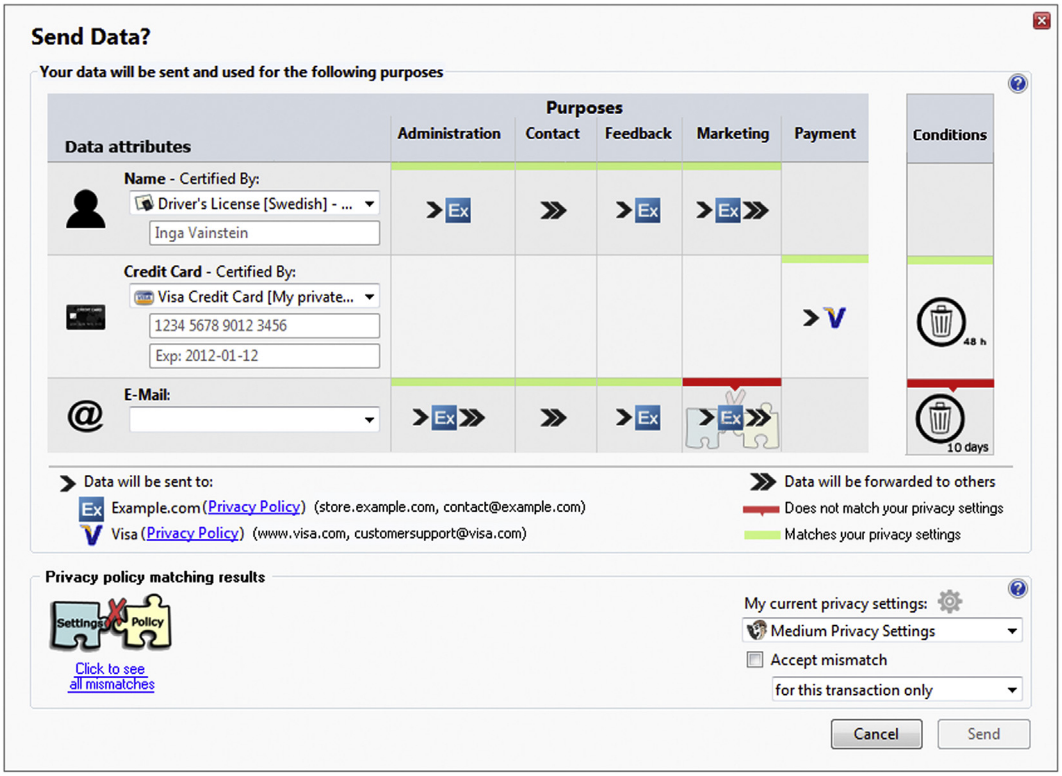

FIGURE 43.7 "Send Data?" PPL user interface [48].

label design more accurately and quickly (see [46]). A more advanced policy language, the PrimeLife Policy Language (PPL), was developed in the EU FP7 project PrimeLife [47]. PPL is a language used to specify not only the privacy policies of data controllers but also those of third parties (so-called downstream controllers) to whom data are further forwarded as well as privacy preferences of users. It is based on two widespread industry standards, XACML (eXtensible Access Control Markup Language) and SAML (Security Assertion Markup Language). The data controller and downstream data controller have policies basically specifying which data are requested from the user and for which purposes and obligations (e.g., under the obligation that the data will be deleted after a certain time period). PPL allows specifying both uncertified data requests and certified data requests based on proofs of the possession of (anonymous IdeMix or traditional X.509) credentials that fulfill certain properties. The user's preferences allow expressing for each data item to which data controllers and downstream data controllers the data can be released and how the user expects his data to be treated. The PPL engine conducts an automated matching of the data controller's policy and the user's preferences. The result can be a mutual agreement concerning the usage of data in the form of a so-called sticky policy, which should be enforced by the access control systems at the backend sides and which will "travel" with the data transferred to downstream controllers.

As PPL has many features that P3P does not provide (downstream data controllers, credential selection for certified data, and obligations), the design of usable PPL user interfaces provides many challenges. The "Send Data?" user interfaces for letting the PPL engine interact with the user for displaying the result of policy matches, identity/credential selection and for obtaining informed consent to disclose selected certified and uncertified data items were developed and presented [48]. Figure 43.7 depicts an example PPL "Send Data?" dialogue.

The PPL user interfaces follow the Art. 29 Data Protection Working Party recommendation of providing policy information in a multilayered format [49] for making policies more understandable and usable. According to this recommendation, a short privacy notice on the top layer offers individuals the core information required under Art. 10 EU Directive 95/46/EC, including at least the identity of the service provider and the purpose of data processing. In addition, a clear indication (in the form of URLs—in our example the "privacy policy" URLs of the two data controllers) must be given as to how the individuals can access the other layers presenting the additional information required by Art. 10 and national privacy laws.

Ex-Post Transparency-Enhancing Tools[8]

An important transparency-enhancing tool that falls into categories 2 and 3 of our classification is the data track that has been developed in the PRIME[9] and PrimeLife[10] projects [51]. The data track is a user side transparency tool, which includes both a history function and online access functions. The history function keeps for each transaction, in which a user discloses personal data to a communication partner, a record for the user on which personal data are disclosed to whom (the identity of the controller), for which purposes, which credentials and/or pseudonyms have been used in this context, as well as the details of the negotiated or given privacy policy. These transaction records are either stored at the user side or centrally (in the Cloud—see [52]) in a secure and privacy-friendly manner. User-friendly search functionalities, which allow the user to easily get an overview about who has received what data about him or her, are also included. The Online access functions allow end users to exercise their rights to access their data at the remote services sides online. In this way, they can compare what data they have disclosed to a services side with what data are still stored by the services side. This allows them to check whether data have been changed, processed, or deleted (in accordance with data retention periods of the negotiated or given privacy policy). Online access is granted to a user if he can provide a unique transaction ID (currently implemented as a 16-byte random number), which is shared between the user (stored in his data track) and the services side for each transaction of personal data disclosure. This in principle also allows anonymous or pseudonymous users to access their data.

While the data track is still in the research prototype stage, the Google Dashboard is already available in practice and grants its users access to a summary of the data stored with a Google account, including account data and the users' search query history, which are, however, only a part of the personal data that Google processes. It does not provide any insight into how these data provided by the users (the users' search queries) have subsequently been processed by Google. Besides, access is provided only to authenticated Google users.

Further examples of transparency tools that allow users to view and control how their personal data have been processed and to check whether this is in compliance with a negotiated or given privacy policy are based on secure logging systems that usually extend the Kelsey-Schneier log [53] and protect the integrity and the confidentiality of the log data. Such a secure logging system and an automated privacy audit facility are key components of a privacy evidence approach proposed by [54]. This privacy evidence system allows a user to inspect all log entries that are recording actions of that user with a special view tool and permits sending the log view created by that tool to the automated privacy audit component, which compares the log view with the privacy policy and to construct privacy evidence. This privacy evidence indicates to the user whether the privacy policy has been violated.

The unlinkability of log entries, which means that they should not be stored in the sequence of their creation, is needed to prevent an adversary from correlating the log with other information sources, such as other external logs, which could allow him to identify data subjects to whom the entries refer (cf. [55]). Also, anonymous access is needed to prevent an adversary from observing who views which log entries and in this way conclude to whom the log entries refer. Wouters et al. [56] have presented such a secure and privacy-friendly Logging for eGovernment Services. However, it addresses the unlinkability of logs between logging systems in eGovernment rather than the unlinkability of log entries within a log. Moreover, it does not address insider attacks, nor does it allow anonymous access to log entries.

Within the PrimeLife project, a secure logging system has been developed, which addresses these aspects of the unlinkability of log entries and anonymous user access. In particular, it fulfills the following requirements (see [55]):

- Only the data subject can decrypt log entries after they have been committed to the log.
- A user can check the integrity of his log entries. A service provider can check the integrity of the whole log file.
- It is not possible for an attacker to secretly modify log entries, which have been committed to the log before the attacker took over the system (forward integrity).
- It is practically impossible to link log entries, which refer to the same user.
- For efficiency reasons, it should be possible for a data subject to read his log entries without the need to download and/or fully traverse the whole log database.

The need and requirements of tools that can anticipate profiles (category 4 of our definition above) have been analyzed within studies of the FIDIS project (see, for instance, [57]). To the best of our knowledge, no practical transparency-enhancing tools fulfill the requirements. In academia, promising approaches [58,59] have been formulated and are the subject of research.

8. SUMMARY

This chapter has provided an introduction to the area of privacy-enhancing technologies. We presented the legal foundation of PETs and provided a classification of PETs, as well as a selection of some of the most relevant PETs. Following the Privacy by Design paradigm for effectively protecting privacy, privacy protection should be incorporated into the overall system design (it should be embedded throughout the entire system life cycle).

While technical PET solutions to many practical privacy issues have existed for many years, these solutions have not been widely adopted by either industry or users. The main factors contributing to this problem are low demand by industry, which, rather, is under competitive business pressure to exploit and monetize user data, and low user awareness in combination with a lack of easily usable, efficient PET implementations (see also [60]). While this chapter is part of a technical computer security handbook and has therefore focused on the technical (and partly legal) aspects of PETs, clearly the economic, social, and usability aspects of PETs also need further attention in the future.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Data protection concerns the protection of personal data in order to guarantee privacy and is only a part of the concept of privacy.
2. True or False? Personal data processing has to be legitimate, which according to Art. 7 EU Directive 95/46/EC is usually the case if the data subject[11] has given his ambiguous (and informed) consent, if there is a legal obligation, or if there is contractual agreement (cf. the Collection Limitation Principle of the OECD Guidelines).
3. True or False? Personal data must be collected for specified, explicit, and legitimate purposes and may be further processed in a way incompatible with these purposes (Art. 6 I b EU Directive 95/46/EC).
4. True or False? The processing of personal data must not be limited to data that are adequate, relevant and not excessive (Art. 6 I (c) EU Directive 95/46/EC).
5. True or False? Transparency of data processing means informing a data subject about the purposes and circumstances of data processing, identifying who is requesting personal data, how the personal data flow, where and how long the data are stored, and what type of rights and controls the data subject has in regard to his personal data.

11. A data subject is a person about whom personal data is processed.

Multiple Choice

1. What needs to install appropriate technical and organizational security mechanisms to guarantee the confidentiality, integrity, and availability of personal data (Art. 17 EU Directive 95/46/EC)?
   - **A.** Privacy-enhancing technology
   - **B.** Location technology
   - **C.** Web-based
   - **D.** Technical improvement
   - **E.** Data controller
2. What can be defined as technologies that are enforcing legal privacy principles in order to protect and enhance the privacy of users of information technology (IT) and/or data subjects?
   - **A.** Information technology
   - **B.** Location technology
   - **C.** Web-based
   - **D.** Privacy-enhancing technologies
   - **E.** Web technology
3. What as an abstract strategy describes the avoidance of unnecessary or unwanted data disclosures?
   - **A.** Data minimization
   - **B.** *XACML*
   - **C.** XML-based language
   - **D.** Certification authority
   - **E.** Security
4. What aim quantifies the effectiveness of schemes or technologies with regard to the privacy goals defined in the previous section?
   - **A.** Privacy metrics
   - **B.** Languages
   - **C.** Privacy-Aware Access Control
   - **D.** Privacy preferences
   - **E.** Taps
5. What is a prerequisite for achieving anonymity, more generally, or data minimization, on an application level?
   - **A.** Release policies
   - **B.** Anonymous communication
   - **C.** Data-handling policies
   - **D.** Intellectual property
   - **E.** Social engineering

EXERCISE

Problem

Why now? Why is the National Strategy for Trusted IDs in Cyberspace needed?

Hands-On Projects

Project

Won't having a single password and credential be less secure and private than having many usernames and passwords?

Case Projects

Problem

Who will make sure that companies follow the rules?

Optional Team Case Project

Problem

Will new laws be needed to create the Identity Ecosystem?

Personal Privacy Policies[1]

1. INTRODUCTION

The rapid growth of the Internet has been accompanied by a similar rapid growth in Internet based e-services targeting consumers. E-services are available for banking, shopping, stock investing, and healthcare, to name a few areas. However, each of these services requires a consumer's personal information in one form or another. This leads to concerns over privacy.

For e-services to be successful, privacy must be protected. In a recent U.S. study by MasterCard International, 60% of respondents were concerned with the privacy of transmitted data.[2] An effective and flexible way of protecting privacy is to manage it using privacy policies. In this approach, each provider of an e-service has a privacy policy specifying the private information required for that e-service. Similarly, each consumer of an e-service has a privacy policy specifying the private information she is willing to share for the e-service. Prior to the activation of an e-service, the consumer and provider of the e-service exchange privacy policies. The service is only activated if the policies are compatible (we define what "compatible" means in a moment). Where the personal privacy policy of an e-service consumer conflicts with the privacy policy of an e-service provider, we have advocated a negotiations approach to resolve the conflict.[3,4]

In our approach, the provider requires private information from the consumer for use in its e-service and so reduces the consumer's privacy by requesting such information. This reduction in consumer privacy is represented by the requirements for consumer private information in the provider's privacy policy. The consumer, on the other hand, would rather keep her private information to herself, so she tries to resist the provider's attempt to reduce her privacy. This means that the consumer would only be willing to have her privacy reduced by a certain amount, as represented by the privacy provisions in her privacy policy. There is a *match* between a provider's privacy policy and the corresponding consumer's policy where the amount of privacy reduction allowed by the consumer's policy is at least as great as the amount of privacy reduction required by the provider's policy (more details on policy matching follow). Otherwise, there is a *mismatch*. Where time is involved, a private item held for less time is considered less private. A privacy policy is considered *upgraded* if the new version represents more privacy than the prior version. Similarly, a privacy policy is considered *downgraded* if the new version represents less privacy than the prior version.

So far so good, but what should go into a personal privacy policy? How are these policies constructed? Moreover, what can be done to construct policies that do not lead to negative unexpected outcomes (an outcome that is harmful to the user in some manner)? Consumers need help in formulating personal privacy policies. The creation of such policies needs to be as easy as possible or consumers would simply avoid using them. Existing privacy specification languages such as P3P and APPEL[5,6]

that are XML-based are far too complicated for the average Internet user to understand. Understanding or changing a privacy policy expressed in these languages effectively requires knowing how to program. What is needed is an easy, semiautomated way of deriving a personal privacy policy.

In this chapter, we present two semiautomated approaches for obtaining personal privacy policies for consumers. We also show how these policies should be specified to avoid negative unexpected outcomes. Finally, we describe our Privacy Management Model that explains how personal privacy policies are used to protect consumer privacy, including how policies may be negotiated between e-service consumer and e-service provider.

The "Content of Personal Privacy Policies" section examines the content of personal privacy policies by identifying some attributes of private information collection. The "Semiautomated Derivation of Personal Privacy Policies" section shows how personal privacy policies can be semiautomatically generated. The "Specifying Well-Formed Personal Privacy Policies" section explains how to ensure that personal privacy policies do not lead to negative unexpected outcomes. "The Privacy Management Model" section presents our Privacy Management Model, which explains how personal privacy policies can be used to protect consumer privacy, including how they may be negotiated between e-service consumer and e-service provider. The "Discussion and Related Work" section discusses our approaches and presents related work. The chapter ends with conclusions and a description of possible future work in these areas.

2. CONTENT OF PERSONAL PRIVACY POLICIES

In Canada, privacy legislation is enacted in the *Personal Information Protection and Electronic Documents Act* (PIPEDA)[7] and is based on the Canadian Standards Association's Model Code for the Protection of Personal Information,[8] recognized as a national standard in 1996. This code consists of ten Privacy Principles that for convenience, we label CSAPP.

Privacy Legislation and Directives

Data privacy in the European Union is governed by a very comprehensive set of regulations called the Data Protection Directive.[9] In the United States, privacy protection is achieved through a patchwork of legislation at the federal and state levels. Privacy legislation is largely sector-based.[10]

Requirements from Privacy Principles

In this section, we identify some attributes of private information collection or personally identifiable information (PII) collection using CSAPP as a guide (see checklist, "An Agenda For Action For Developing Privacy Policies To Guide Customer /Client Relations"). We then apply the attributes to the specification of privacy policy contents. Note that we use the terms *private information* and *PII* interchangeably. We use CSAPP because it is representative of privacy legislation in other countries (European Union, Australia) and has withstood the test of time, originating from 1996. In addition, CSAPP is representative of the Fair Information Practices, a set of standards balancing the information needs of the business with the privacy needs of the individual.[11] Table 44.1 shows CSAPP.

In Table 44.1, we interpret *organization* as "provider" and *individual* as "consumer." In the following, we use CSAPP.*n* to denote Principle *n* of CSAPP. Principle CSAPP.2 implies that there could be different providers requesting the information, thus implying a *collector* attribute. Principle CSAPP.4 implies that there is a *what* attribute, that is, what private information is being collected? Principles CSAPP.2, CSAPP.4, and CSAPP.5 state that there are *purposes* for which the private information is being collected. Principles CSAPP.3, CSAPP.5, and CSAPP.9 imply that the private information can be disclosed to other parties, giving a *disclose-to* attribute. Principle CSAPP.5 implies a *retention time* attribute for the retention of private information. Thus, from the CSAPP we derive five attributes of private information collection: *collector, what, purposes, retention time*, and *disclose-to*.

The Privacy Principles also prescribe certain operational requirements that must be satisfied between provider and consumer, such as identifying purpose and consent. Our service model and the exchange of privacy

An Agenda for Action for Developing Privacy Policies to Guide Customer /Client Relations

The checklist suggests issues to consider when drafting privacy principles to safeguard the personal information of your clients and customers: (Check All Tasks Completed):

A. Organizational Policies:

_____**1.** Does your organization have policies that outline its privacy practices and expectations for handling the personal information of its clients, customers, users, members and/or listees?

_____**2.** Are your organization's privacy policies communicated regularly? Opportunities include in employees' initial training sessions, in regular organization-wide training programs, in employee handbooks, on posters and posted signs, on company intranet and Internet Web sites, in brochures available to clients.

_____**3.** Are all employees who handle personal information included in the training programs, including temporary employees, back-up personnel, and contract staff?

_____**4.** Is your organization familiar with and has it adopted International Standards Organization (ISO) security standards, known as ISO 27001?

B. Privacy Principles:

_____**5.** **Openness.** A general practice of openness about practices and policies should exist. Means should be available to establish the existence and nature of personal information and the main purposes of its use.

_____**6.** **Purpose specification.** The purpose for collecting personal information should be specified at the time of collection. Further uses should be limited to those purposes.

_____**7.** **Collection limitation.** Personal information should be collected by lawful and fair means and with the knowledge and consent of the subject. To the greatest extent possible, companies should employ principles of data minimization, that is, collecting only data that is actually necessary to conduct their business, and collecting such information only for the stated purpose.

_____**8.** **Use limitation.** Personal information should not be disclosed for secondary purposes without the consent of the subject or by authority of law.

_____**9.** **Individual participation.** Individuals should be allowed to inspect and correct their personal information. Whenever possible, personal information should be collected directly from the individual.

_____**10.** **Quality.** Personal information should be accurate, complete and timely, and be relevant to the purposes for which it is to be used.

_____**11.** **Security safeguards.** Personal information should be protected by reasonable security safeguards against such risks as loss, unauthorized access, destruction, use, modification or disclosure. Access to personal information should be limited to only those within the organization with a specific need to see it.

_____**12.** **Accountability.** Someone within the organization, such as the chief privacy officer or an information manager, should be held accountable for complying with its privacy policy. Privacy audits to monitor organizational compliance should be conducted on a regular basis, as should employee training programs.

C. Data and Network Security:

_____**13.** Do you have staff specifically assigned to data security?

_____**14.** Do staff members participate in regular training programs to keep abreast of technical and legal issues?

_____**15.** Have you developed a security breach response plan in the event that your company or organization experiences a data breach?

_____**16.** Have you developed security guidelines for laptops and other portable computing devices when transported off-site?

_____**17.** Is physical access restricted to computer operations and paper/micrographic files that contain personally identifiable information?

_____**18.** Do you have procedures to prevent former employees from gaining access to computers and paper files?

_____**19.** Are sensitive files segregated in secure areas/computer systems and available only to qualified persons?

_____**20.** Are filing cabinets containing sensitive information locked? Are computers, laptops, and networks password protected?

_____**21.** Do you have audit procedures and strict penalties in place to prevent telephone fraud and theft of equipment and information?

_____**22.** Do all employees follow strict password and virus protection procedures?

_____**23.** Are employees required to change passwords often, using "foolproof" methods?

_____**24.** Is encryption used to protect sensitive information (a particularly important measure when transmitting personally-identifiable information over the Internet)?

_____**25.** Do you regularly conduct systems-penetration tests to determine if your systems are hacker proof?

_____**26.** If your organization is potentially susceptible to industrial espionage, have you taken extra precautions to guard against leakage of information?

TABLE 44.1 CSAPP: The Ten Privacy Principles from the Canadian Standards Association.

Principle	Description
1. Accountability	An organization is responsible for personal information under its control and shall designate an individual or individuals accountable for the organization's compliance with the privacy principles.
2. Identifying Purposes	The purposes for which personal information is collected shall be identified by the organization at or before the time the information is collected.
3. Consent	The knowledge and consent of the individual are required for the collection, use, or disclosure of personal information, except when inappropriate.
4. Limiting Collection	The collection of personal information shall be limited to that which is necessary for the purposes identified by the organization. Information shall be collected by fair and lawful means.
5. Limiting Use, Disclosure, and Retention	Personal information shall not be used or disclosed for purposes other than those for which it was collected, except with the consent of the individual or as required by the law. In addition, personal information shall be retained only as long as necessary for fulfillment of those purposes.
6. Accuracy	Personal information shall be as accurate, complete, and up to date as is necessary for the purposes for which it is to be used.
7. Safeguards	Security safeguards appropriate to the sensitivity of the information shall be used to protect personal information.
8. Openness	An organization shall make readily available to individuals specific information about its policies and practices relating to the management of personal information.
9. Individual Access	Upon request, an individual shall be informed of the existence, use and disclosure of his or her personal information and shall be given access to that information. An individual shall be able to challenge the accuracy and completeness of the information and have it amended as appropriate.
10. Challenging Compliance	An individual shall be able to address a challenge concerning compliance with the above principles to the designated individual or individuals accountable for the organization's compliance.

policies automatically satisfy some of these requirements, namely Principles CSAPP.2, CSAPP.3, and CSAPP.8. The satisfaction of the remaining operational requirements depends on compliance mechanisms (Principles CSAPP. 1, CSAPP.4, CSAPP.5, CSAPP.6, CSAPP.9, and CSAPP. 10) and security mechanisms (Principle CSAPP.7).

Privacy Policy Specification

Based on these explorations, the contents of a privacy policy should, for each item of PII, identify (1) the *collector*—the person who wants to collect the information, (2) *what*—the nature of the information, (3) *purposes*—the purposes for which the information is being collected, (4) *retention time*—the amount of time for the provider to keep the information, and (5) *disclose-to*—the parties to whom the information will be disclosed. Figure 44.1 gives three examples of consumer personal privacy policies for use with an e-learning provider, an online bookseller, and an online medical help clinic. The *policy use* field indicates the type of online service for which the policy will be used. Since a privacy policy may change over time, we have a *valid* field to hold the time period during which the policy is valid. Figure 44.2 gives examples of provider privacy policies corresponding to the personal privacy policies of Figure 44.1.

A privacy policy thus consists of "header" information *(policy use, owner, valid)* together with one or more 5-tuples, or privacy rules:

$$< collector, what, purposes, retention\,time, disclose-to >$$

where each 5-tuple or rule represents an item of private information and the conditions under which the information may be shared. For example, in Figure 44.1, the personal policy for e-learning has a header (top portion) plus two rules (bottom portion); the personal policy for a bookseller has only one rule.

3. SEMIAUTOMATED DERIVATION OF PERSONAL PRIVACY POLICIES

A semiautomated derivation of a personal privacy policy is the use of mechanisms (described in a moment) that may

Policy Use: E-learning *Owner*: Alice Consumer *Valid*: unlimited	*Policy Use*: Bookseller *Owner*: Alice Consumer *Valid*: June 2009	*Policy Use*: Medical Help *Owner*: Alice Consumer *Valid*: July 2009
Collector: any *What*: name, address, tel *Purposes*: identification *Retention Time*: unlimited *Disclose-To*: none *Collector*: any *What*: course marks *Purposes*: records *Retention Time*: 2 years *Disclose-To*: none	*Collector*: any *What*: name, address, tel *Purposes*: identification *Retention Time*: unlimited *Disclose-To*: none	*Collector*: any *What*: name, address, tel *Purposes*: contact *Retention Time*: unlimited *Disclose-To*: pharmacy *Collector*: Dr. A. Smith *What*: medical condition *Purposes*: treatment *Retention Time*: unlimited *Disclose-To*: pharmacy

FIGURE 44.1 Example of consumer personal privacy policies.

Policy Use: E-learning *Owner*: E-learning Unlimited *Valid*: unlimited	*Policy Use*: Bookseller *Owner*: All Books Online *Valid*: unlimited	*Policy Use*: Medical Help *Owner*: Medics Online *Valid*: unlimited
Collector: E-learning Unlimited *What*: name, address, tel *Purposes*: identification *Retention Time*: unlimited *Disclose-To*: none *Collector*: E-learning Unlimited *What*: course marks *Purposes*: records *Retention Time*: 1 years *Disclose-To*: none	*Collector*: All Books Online *What*: name, address, tel *Purposes*: identification *Retention Time*: unlimited *Disclose-To*: none *Collector*: All Books Online *What*: credit card *Purposes*: payment *Retention Time*: until paid *Disclose-To:* none	*Collector*: Medics Online *What*: name, address, tel *Purposes*: contact *Retention Time*: unlimited *Disclose-To*: pharmacy *Collector*: Medics Online *What*: medical condition *Purposes*: treatment *Retention Time*: 1 year *Disclose-To*: pharmacy

FIGURE 44.2 Example of corresponding provider privacy policies.

be semiautomated to obtain a set of privacy rules for a particular policy use. We present two approaches for such derivations. The first approach relies on third-party surveys (see sidebar, "Derivation Through Third Party Surveys") of user perceptions of data privacy (Figure 44.3). The second approach is based on retrieval from a community of peers.

Consumers may interactively adapt their existing privacy policies for new service provider policies based on the PSLs of the WPRs and the new provider policies, as illustrated in Figure 44.4. In Figure 44.4, the Policy Interpreter interactively allows the user to establish (using a privacy slider) the privacy levels of required rules based on the new provider policy and the PSLs from a policy provider. Policy Search then retrieves the user policy that most closely matches the user's privacy-established rules. This policy may then be further amended interactively via the Policy Interpreter to obtain the required personal privacy policy. This assumes the availability of an easy-to-understand interface for the user interaction as well as software to automatically take care of any needed conversions of rules back into the policy language (APPEL).

An Example

Suppose a consumer wants to generate a personal privacy policy for a company called E-learning Unlimited. For simplicity, suppose the privacy policy of E-learning Unlimited has only one WPR, namely < *course marks, records, 12 months* >. The steps are implemented as follows:

1. The third-party survey generates the following results for the WPR (the lowest privacy sensitivity level is $M = 1$, the highest is $N = 5$).
   WPR (p_i) PSL ($S_{k,i}$)
   < *course marks, records, 6 months* > 3
   < *course marks, records, 6 months* > 4
   < *course marks, records, 6 months* > 4
   < *course marks, records, 6 months* > 5
   < *course marks, records, 12 months* > 1
   < *course marks, records, 12 months* > 1
   < *course marks, records, 12 months* > 2
   < *course marks, records, 12 months* > 3
   Note that the higher the number of months the marks are retained, the lower the PSL (the lower

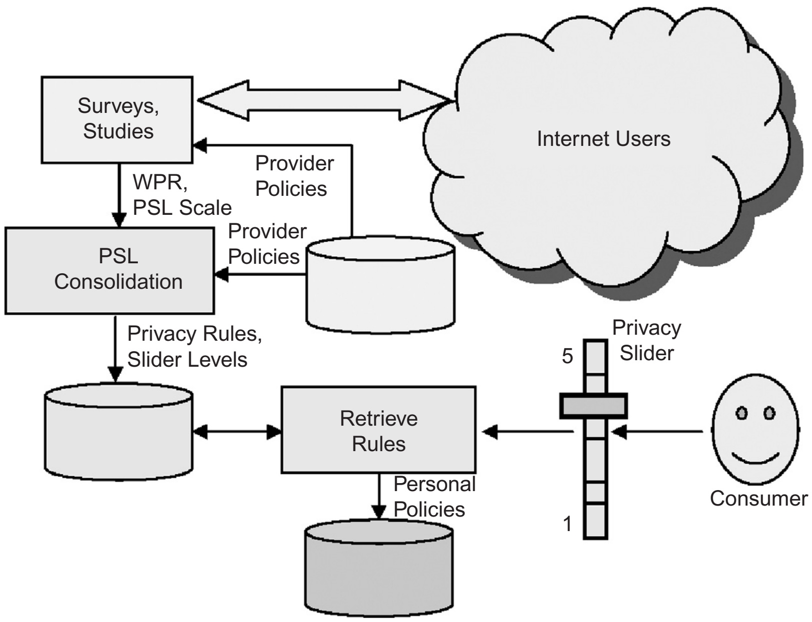

FIGURE 44.3 Derivation of personal privacy policies from surveys.

Derivation Through Third-Party Surveys

(a) A policy provider makes use of third-party surveys performed on a regular basis, as well as those published in research literature, to obtain user privacy sensitivity levels (PSLs) or perceptions of the level of privacy for various combinations of $<$*what, purposes, retention time*$>$ in provider policy rules. We call $<$*what, purposes, retention time*$>$ *WPR*, for short. This gives a range of PSLs for different WPRs in different provider policies. Formally:

Let p_i represent a WPR from a provider policy, I represent the set of p_i over all provider policies, $f_{k,i}$ represent the privacy sensitivity function of person k to sharing p_i with a service provider. We restrict $f_{k,i}$ to an integer value in a standard interval $[M,N]$, that is, $M \le f_{k,i} \le N$ for integers M, N (e.g., $M=1$, $N=5$). Then the PSLs $s_{k,i}$ are obtained as

$$s_{k,i} = f_{k,i}(p_i) \forall k \in K, i \in I$$

where K is the set of consumers interested in the providers' services. This equation models a person making a choice of what PSL to assign a particular p_i.

(b) Corresponding to a service provider's privacy policy (which specifies the privacy rules required), a policy provider (or a software application used by the policy provider) consolidates the PSLs from (a) such that the WPRs are selectable by a single value privacy level from a "privacy slider" for each service provider policy. There are different ways to do this consolidation. One way is to assign a WPR the median of its PSL range as its privacy level (illustrated in a moment). The outcome of this process is a set of consumer privacy rules (expressed using a policy language such as APPEL) ranked by privacy level for different providers, and with the *collector* and *disclose-to* fields as "any" and "none," respectively. (The consumer can change these fields later if desired.) Formally, using the notation introduced in (a):

Let P represent a provider's privacy policy. Then for each WPR $p_i \in P$, we have from (a) a set of PSLs: $S_i(P) = \{s_{k,i} \mid p_i \in P, \forall k \in K\}$. Our goal is to map $S_i(P)$ to a single privacy level from a privacy slider. Let g be such a mapping. Then this step performs the mapping $g(S_i(P)) = n$, where n is the privacy slider value. For example, the mapping g can be "take the median of" (illustrated below) or "take the average of." We have assumed that the range of slider values is the same as $[M,N]$ in (a). If this is not the case, g would need to incorporate normalization to the range of slider values.

(c) Consumers obtain online from the policy provider the privacy rules that make up whole policies. They do this by first specifying the provider for which a consumer privacy policy is required. The consumer is then prompted to enter the privacy level using the privacy slider for each WPR from the service provider's policy. The selected rules would then automatically populate the consumer's policy. The consumer then completes his privacy policy by adding the header information (i.e., *policy use, owner, valid)* and, if desired, add specific names to *collector* and *disclose-to* for all rules. This can be done through a human-computer interface that shelters the user from the complexity of the policy language. In this way, large populations of consumers may quickly obtain privacy policies for many service providers that reflect the privacy sensitivities of the communities surveyed.

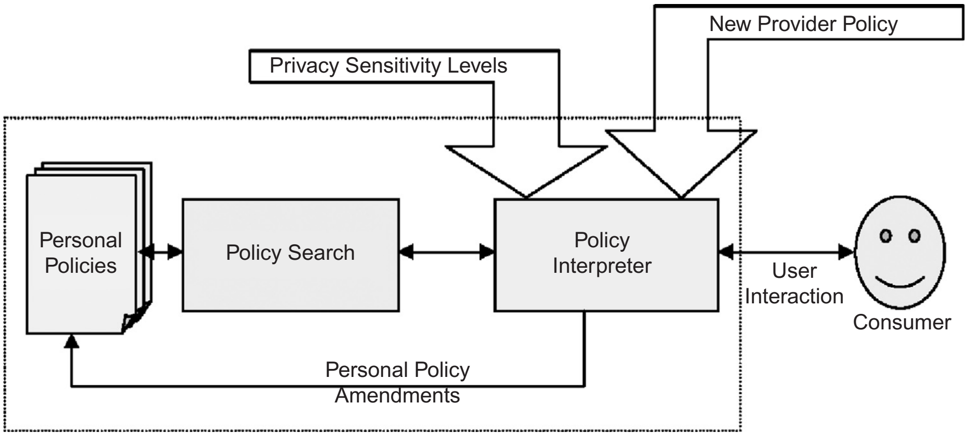

FIGURE 44.4 Adapting an existing personal privacy policy to a new provider.

the privacy perceived by the consumer). The different PSLs obtained constitute one part of the privacy sensitivity scale.

2. In this step, the policy provider consolidates the PSL in Step 1 using the median value from the corresponding PSL range. Thus for the four course-mark retention times of 6 months, the lowest value is 3, the highest value is 5, and the median is 4. Therefore the rule <*any, course marks, records, 6 months, none*> is ranked with privacy level 4. Similarly, the rule <*any, course marks, records, 12 months, none*> is ranked with privacy level 2.
3. To obtain her privacy rules, the consumer specifies the service provider as E-learning Unlimited and a privacy slider value of 4 (for example) when prompted. She then obtains the rule:
   <*any, course marks, records, 6 months, none*>
   and proceeds to complete the policy by adding the header values and if desired, specific names for *collector* and *disclose-to*.

Retrieval from a Community of Peers

This approach assumes an existing community of peers already possessing specific use privacy policies with rules according to desired levels of privacy. A new consumer joining the community searches for personal privacy rules. The existing personal privacy policies may have been derived using the third-party surveys, as previously. Each privacy policy rule is stored along with its privacy level so that it may be selected according to this level and *purpose*. Where a rule has been adapted or modified by the owner, it is the owner's responsibility to ensure that the slider privacy value of the modified rule is consistent with the privacy sensitivity scale from surveys.

- All online users are peers and everyone has a privacy slider. The new consumer broadcasts a request for privacy rules to the community (see Figure 44.5a), specifying *purpose* and slider value. This is essentially a peer-to-peer search over all peers.
- The community responds by forwarding matching (in terms of *purpose* and slider value) rules to the consumer (see Figure 44.5b). This matching may also be fuzzy.
- The consumer compares the rules and selects them according to *what*, possibly popularity (those that are from the greater number of peers), and best fit in terms of privacy. After obtaining the rules, the consumer completes the privacy policies by completing the headers and possibly changing the *collector* and *disclose-to* as in the preceding derivation from surveys approach.
- The consumer adapts a privacy policy to the service provider's policy, as in the derivation by surveys approach (Figure 44.4), to try to fulfill provider requirements.

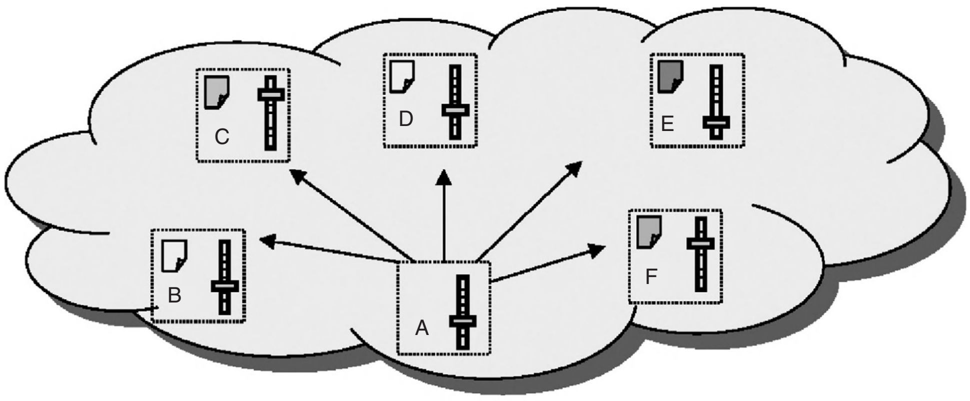
4. SPECIFYING WELL-FORMED PERSONAL PRIVACY POLICIES

This section explains how unexpected outcomes may arise from badly specified personal privacy policies. It then gives guidelines for specifying "well-formed" policies that avoid unexpected outcomes.

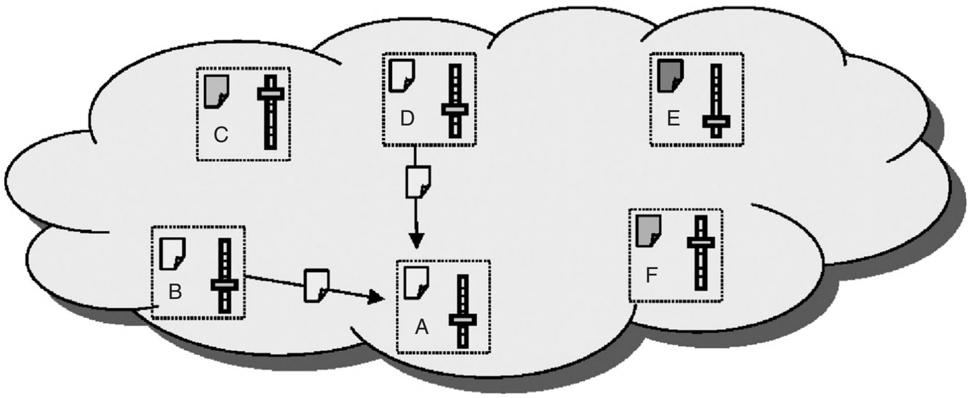
Unexpected Outcomes

We are interested in unexpected outcomes that result from the matching of consumer and provider policies. Unexpected outcomes result from (1) the way the matching policy was obtained, and (2) the content of the matching policy itself. We examine each of these sources in turn.

FIGURE 44.5 Retrieval of private policy rules from a community of peers.



(a) New consumer "A" broadcasts request for privacy rules to the community



(b) Consumers B and D answer A's request

Outcomes from the Way the Matching Policy was Obtained

The matching policy can be obtained through policy upgrades or downgrades. These policy changes can occur while the policy is being formulated for the first time or after a mismatch occurs, in an attempt to obtain a match (during policy negotiation[12,13]). Recall from the "Introduction" section that an upgraded policy reflects a higher level of privacy. On the other hand, a downgraded policy reflects a lower level of privacy.

Policy Upgrades

Given that a provider always tries to reduce a consumer's privacy, it is possible that the policy nonmatch was due to the provider's policy requiring too much privacy reduction. Suppose then that the match occurred after the provider upgraded its privacy policy to represent more privacy, that is, require less privacy reduction. This could mean that the provider is requiring less information that is private. In this case, the provider or consumer may not realize the extra costs that may result from not having access to the private information item or items that were eliminated through upgrading. For example, leaving out the social security number may lead to more costly means of consumer identification for the provider. As another example, consider the provider and consumer policies of Figure 44.6. In this figure, suppose All Books Online upgraded its privacy policy by eliminating the credit-card requirement. This would lead to a match with Alice's privacy policy, but it could cost Alice longer waiting time to get her order, since she may be forced into an alternate and slower means of making payment (e.g., mailing a check) if payment is required prior to shipping.

Policy Downgrades

Since the consumer resists the provider's privacy reduction, it is possible that the policy nonmatch was due to

Smith *What*: medical condition *Purposes*: treatment *Retention Time*: unlimited *Disclose-To*: pharmacy

FIGURE 44.7 Example of medical help provider (left) and consumer privacy policies (right).

the consumer's policy allowing too little privacy reduction. Suppose then that the match occurred after the consumer downgraded her privacy policy to represent less privacy, that is, to allow for more privacy reduction. This could mean that the consumer is willing to provide more information that is private. Then the provider or consumer may not realize the extra costs that result from having to safeguard the additional private information item or items that were added through downgrading. For example, the additional information might be a critical health condition that the consumer does not want anyone else to know, especially her employer, which could result in loss of her employment. The provider had better add sufficient (costly) safeguards to make sure that the condition is kept confidential. The provider may not have fully realized the sensitivity of the extra information.

Outcomes from the Content of the Matching Policy

We give here some example unexpected outcomes due to the content of the matching policy. We examine the content of the header and privacy rules in turn, as follows.

Valid Field

If the *valid* field of the consumer's policy is not carefully specified, the provider may become confused upon expiry if there is not another consumer policy that becomes the new policy. In this state of confusion the provider could inadvertently disclose the consumer's private information to a party that the consumer does not want to receive the information.

Collector Field

Specification of who is to collect the consumer's private information needs to consider what happens if the collector is unavailable to receive the information. For example, consider the privacy policies of Figure 44.7. The policies are not compatible, since Alice will reveal her medical condition only to Dr. Smith, whereas the provider would like any doctor or nurse on staff to take the information. Suppose the provider upgrades its policy to satisfy Alice by allowing only Dr. Smith to receive information on Alice's condition. Then an unexpected outcome is that Alice cannot receive help from Nursing Online because Dr. Smith is not available (he might have been seriously injured in an accident), even though the policies would match and the service could theoretically proceed. There are various ways to solve this particular situation (one way is simply to have an overriding condition that in an emergency, Alice *must* give her condition to any doctor or nurse on staff), but our point still holds: An improperly specified *collector* attribute can lead to unexpected serious consequences.

Retention Time

Care must also be taken to specify the appropriate retention time for a particular information item. The responsibility for setting an appropriate retention time lies with both the provider and the consumer. For example, consider once again the policies of Figure 44.7. Suppose Alice changes her privacy rule for medical condition from *Dr. A. Smith* to *any* and from *unlimited* to *2 years*. Then the policies match and the service can proceed. At the end of two years, the provider complies with the consumer's privacy policy and discards the information it has on Alice's medical condition. But suppose that after the two years, medical research discovers that Alice's

condition is terminal unless treated with a certain new drug. Then Nursing Online cannot contact Alice to warn her, since it no longer knows that Alice has that condition. Poor Alice! Clearly, both the provider and the consumer are responsible for setting the appropriate retention time. One could conclude that in the case of a medical condition, the retention time should be *unlimited*. However, *unlimited* can also have its risks, such as retaining information beyond the point at which it no longer applies. For example, Alice could one day be cured of her condition. Then retention of Alice's condition could unjustly penalize Alice if it somehow leaked out when it is no longer true.

Disclose-to Field

If the *disclose-to* attribute of the consumer's privacy policy is not specified or improperly specified, providers can share the consumer's private information with other providers or consumers with resulting loss of privacy. Consider the following examples.

Suppose Alice has a critical health condition and she does not want her employer to know for fear of losing her job (the employer might dismiss her to save on sick leave or other benefits—this really happened![14]). Suppose that she is able to subscribe to Nursing Online as in the preceding examples. Then through the execution of the service, Nursing Online shares her condition with a pharmacy to fill her prescription. Suppose the company that Alice works for is a pharmaceutical supplier and needs to know contact information of patients in the area where Alice lives so that the company can directly advertise to them about new drugs effective for Alice's condition. Suppose further that the pharmacy with which Nursing Online shared Alice's condition is a consumer of the pharmaceutical supplier and the pharmacy's privacy policy does not restrict the sharing of patient information that it receives secondhand. Then the pharmaceutical supplier, Alice's employer, can learn of her health condition from the pharmacy, and Alice could lose her job—an unexpected outcome with serious consequences. A possible solution to this situation is for Alice to specify *pharmacy, no further* for *disclose-to*. Then to comply with Alice's policy, Nursing Online, as a consumer of the pharmacy, in its privacy policy with the pharmacy would specify *none* for the *disclose-to* corresponding to Alice's condition, thus preventing Alice's employer from learning of her condition and so preserving her privacy.

As another example, suppose Alice, as a consumer, uses graphics services from company A and company B. Her privacy policy with these companies stipulates that the rates she pays them is private and not to be disclosed to any other party. Suppose she pays company A a higher rate than company B. Now suppose companies A and B are both consumers of company C, which provides data on rates paid for graphics services. To use company C's services, companies A and B must provide company C with deidentified information regarding rates they are paid. This does not violate the privacy policies of consumers of companies A and B, because the information is deidentified. However, company B now learns of the higher rate paid company A and seeks a higher rate from Alice. There does not appear to be any solution to this situation, since Alice has already specified *disclose-to* as *none*. This example shows that there can be unexpected outcomes that may not be preventable.

We have presented a number of unexpected outcomes arising from the way the policy match was obtained and how the content of the policy was specified. Our outcomes are all negative ones because they are the ones we need to be concerned about. There are also, of course, positive unexpected outcomes, but they are outside the scope of this chapter.

5. PREVENTING UNEXPECTED NEGATIVE OUTCOMES

The problem at hand is how to detect and prevent the unexpected outcomes that are negative or dangerous. Since all unexpected outcomes derive from the personal privacy policy (at least in this work), it is necessary to ensure "well-formed" policies that can avoid unexpected negative outcomes. Further, if a non-well-formed policy matches the first time and leads to negative outcomes, it is too late to do anything about it. Based on the discussion of the preceding section, let's define our terms.

Definition 1

An *unexpected negative outcome* is an outcome of the use of privacy policies such that (1) the outcome is unexpected by both the provider and the consumer, and (2) the outcome leads to either the provider or the consumer or both experiencing some loss, which could be private information, money, time, convenience, job, and so on, even losses that are safety and health related.

Definition 2

A *well-formed (WF)* privacy policy (for either consumer or provider) is one that does not lead to unexpected negative outcomes. A *near well-formed (NWF)* privacy policy is one in which the attributes *valid, collector, retention time*, and *disclose-to* have each been considered against

14. J. K. Kumekawa, "Health information privacy protection: crisis or common sense?", retrieved Sept. 7, 2003, from www.nursingworld.org/ojin/topic16/tpc16_2.htm.

all *known* misspecifications that can lead to unexpected negative outcomes.

In Definition 2, the misspecifications can be accumulated as a result of experience (trial and error) or by scenario exploration (as earlier). We have already presented a number of them in the preceding section. An NWF privacy policy is the best that we can achieve at this time. Clearly, such a policy does not guarantee that unexpected negative outcomes will not occur; it just reduces the probability of an unexpected negative outcome.

Rules for Specifying near Well-Formed Privacy Policies

Let's consider once more the content of a personal privacy policy by looking at the header and the privacy rules. The header (Figure 44.1) consists of *policy use, owner*, and *valid. Policy use* and *owner* serve only to identify the policy and, assuming they are accurately specified, they are unlikely to lead to unexpected negative outcomes. That leaves *valid*. As discussed, *valid* must be specified so that it is never the case that the provider is in possession of the consumer's private information without a corresponding valid consumer policy (i.e., with the policy expired). Another way to look at this is that it must be true that the provider is no longer in possession of the consumer's information at the point of policy expiration. Hence we can construct a rule for specifying *valid*.

Rule for Specifying Valid

The time period specified for valid *must be at least as long as the longest retention time in the privacy policy*. This rule ensures that if the provider is in possession of the consumer's private information, there is always a corresponding consumer privacy policy that governs the information, which is what is needed to avoid the unexpected outcomes from an improperly specified *valid*.

Let's now consider the content of a privacy rule. The privacy rule consists of the attributes *collector, what, purposes, retention time*, and *disclose-to* (Figure 44.1). *What* and *purposes* serve only to identify the information and the purposes for which the information will be put to use. Assuming they are accurately specified, they are unlikely to lead to unexpected negative outcomes. That leaves *collector, retention-time*, and *disclose-to*, which we discussed. Based on this discussion, we can formulate specification rules for these attributes.

Rule for Specifying Collector

When specifying an individual for collector, *the consequences of the unavailability of the individual to receive the information must be considered. If the consequences do not lead to unexpected negative outcomes (as far as can be determined), proceed to specify the individual. Otherwise, or if there is doubt, specify the name of the provider (meaning anyone in the provider's organization).*

Rule for Specifying Retention Time

When specifying retention time, *the consequences of the expiration of the retention time (provider destroys corresponding information) must be considered. If the consequences do not lead to unexpected negative outcomes (as far as can be determined), proceed to specify the desired time. Otherwise, or if there is doubt, specify the length of time the service will be used.*

Rule for Specifying Disclose-To

When specifying disclose-to, *the consequences of successive propagation of your information starting with the first party mentioned in the* disclose-to *must be considered. If the consequences do not lead to unexpected negative outcomes (as far as can be determined), proceed with the specification of the* disclose-*to party or parties. Otherwise, or if there is doubt, specify* none *or* name of receiving party, no further.

These rules address the problems discussed in the section "Outcomes from the Content of the Matching Policy" that lead to unexpected negative outcomes. Except for *valid*, in each case we require the consumer or provider to consider the consequences of the intended specification, and propose specification alternatives, where the consequences lead to unexpected negative outcomes or there is doubt. By definition, application of these rules to the specification of a privacy policy will result in a near well-formed policy. Undoubtedly, mathematical modeling of the processes at play together with state exploration tools can help to determine whether or not a particular specification will lead to unexpected negative outcomes. Such modeling and use of tools is part of future research.

Approach for Obtaining Near Well-Formed Privacy Policies

We propose that these rules for obtaining near well-formed policies be incorporated during initial policy specification. This is best achieved using an automatic or semiautomatic method for specifying privacy policies, such as the methods in the section "Semiautomated Derivation of Personal Privacy Policies." The rule for *valid* is easy to implement. Implementation of the remaining rules may employ a combination of artificial intelligence and human-computer interface techniques to assist

the human specifier to reason out the consequences. Alternatively, the rules may be applied during manual policy specification in conjunction with a tool for determining possible consequences of a particular specification.

6. THE PRIVACY MANAGEMENT MODEL

In this part of the chapter, we explain how our Privacy Management Model works to protect a consumer's privacy through the use of personal privacy policies.

How Privacy Policies are Used

An e-service provider has a privacy policy stating what PII it requires from a consumer and how the information will be used. A consumer has a privacy policy stating what PII the consumer is willing to share, with whom it may be shared, and under what circumstances it may be shared. An entity that is both a provider and a consumer has separate privacy policies for these two roles. A privacy policy is attached to a software agent, one that acts for the consumer and another that acts for the provider. Prior to the activation of a particular service, the agent for the consumer and the agent for the provider undergo a privacy policy exchange, in which the policies are examined for compatibility (see Figure 44.8). The service is only activated if the policies are compatible, in which case we say that there is a "match" between the two policies.

The Matching of Privacy Policies

We define here the meaning of a match between a consumer personal privacy policy and a service provider privacy policy. Such matching is the comparison of corresponding rules that have the same *purposes* and similar *what*. Let I represent the set of rules in a consumer privacy policy and let J represent the set of rules in a service provider privacy policy. Let $p_{i,c}$, $i \in I$ and $p_{j,p}$, $j \in J$ represent corresponding WPRs of the consumer policy and the provider policy, respectively, that have the same *purposes* and similar *what*. We want to ascribe a function *pr* that returns a numerical level of privacy from the consumer's point of view when applied to $p_{i,c}$ and $p_{j,p}$. A high *pr* means a high degree of privacy; a low *pr* means a low degree of privacy—from the consumer's point of view. It is difficult to define *pr* universally because privacy is a subjective notion, and one consumer's view of degree of privacy may be different from another consumer's view. However, the privacy rules from the policy provider have corresponding privacy slider values and they are just what we need. We simply look up $p_{i,c}$ and $p_{j,p}$ in the policy provider database and assign the corresponding privacy slider values to them. This look-up and assignment can be done automatically.

Definition 3 (Matching Collector and Disclose-to)

The *collector* parameter from a consumer policy matches the *collector* parameter from a provider policy if and only if they are textually the same or the *collector* parameter from the consumer policy has the value *any*. The matching of *disclose-to* parameters is defined in the same way.

Definition 4 (Matching Rules)

There is a *match* between a rule in a consumer privacy policy and the corresponding (same *purposes* and similar *what*) rule in the provider policy if and only if:

$$pr(p_{i,c}) \le (p_{j,p}), i \in I, j \in J$$

and the corresponding *collector* and *disclose-to* parameters match. If there is no corresponding rule in the provider policy, we say that the consumer rule corresponds to the *null* rule in the provider policy (called *consumer* n-*correspondence*), in which case the rules automatically match. If there is no corresponding rule in the consumer policy, we say that the provider rule corresponds to the *null* rule in the consumer policy (called *provider* n-*correspondence*), in which case the rules automatically mismatch.

In Definition 4, a match means that the level of privacy in the provider's rule is greater than the level of privacy in the consumer's rule (the provider is demanding less information than the consumer is willing to offer). Similarly, a consumer rule automatically matches a provider null rule because it means that the provider is not even asking for the information represented by the consumer's rule (ultimate rule privacy). A provider rule automatically mismatches a consumer null rule because it means the provider is asking for information the consumer is not willing to share, whatever the conditions (ultimate rule lack of privacy).

FIGURE 44.8 Exchange of privacy policies (PP) between consumer agent (CA) and provider agent (PA).

TABLE 44.2 Example Negotiation Dialogue Showing Offers and Counteroffers.

Provider	Employee
Okay for your exam results to be seen by your management?	Yes, but only David and Suzanne can see them.
Okay if only David and Bob see them?	No, only David and Suzanne can see them.
Can management from Divisions B and C also see your exam results?	Okay for management from Division C but not Division B.
How about letting Divisions C and D see your results?	That is acceptable.

Definition 5 (Matching Privacy Policies)

A consumer privacy policy matches a service provider privacy policy if and only if all corresponding (same *purposes* and similar *what*) rules match. And, there are no cases of provider *n*-correspondence, although there may be cases of consumer *n*-correspondence.

Definition 6 (Upgrade and Downgrade of Rules and Policies)

A privacy rule or policy is considered *upgraded* if the new version represents more privacy than the prior version. A privacy rule or policy is considered *downgraded* if the new version represents less privacy than the prior version.

In comparing policies, it is not always necessary to carry out the comparison of each and every privacy rule as required by Definitions 4 and 5. We mention three shortcuts here.

Shortcut 1

Both policies are the same except one policy has fewer rules than the other policy. According to Definitions 4 and 5, there is a match if the policy with fewer rules belongs to the provider. There is a mismatch if this policy belongs to the consumer.

Shortcut 2

Both policies are the same except one policy has one or more rules with less retention time than the other policy. According to Definitions 4 and 5, there is a match if the policy with one or more rules with less retention time belongs to the provider. There is a mismatch if this policy belongs to the consumer.

Shortcut 3

Both policies are the same except one policy has one or more rules that clearly represent higher levels of privacy than the corresponding rules in the other policy. According to Definitions 4 and 5, there is a match if the policy with rules representing higher levels of privacy belongs to the provider. There is a mismatch if this policy belongs to the consumer.

Thus, in our example policies (Figures 44.1 and 44.2), there is a match for e-learning according to Shortcut 2, since the policy with lower retention time belongs to the provider. There is a mismatch for bookseller according to Shortcut 1, since the policy with fewer rules belongs to the consumer. There is a mismatch for medical help according to Shortcut 3, since the policy with the rule representing a higher level of privacy is the one specifying a particular collector (Dr. Smith), and this policy belongs to the consumer.

Personal Privacy Policy Negotiation

Where there is no match between a consumer's personal privacy policy and the privacy policy of the service provider, the consumer and provider may negotiate with each other to try to achieve a match.[15,16] Consider the following negotiation to produce a privacy policy for an employee taking a course from an e-learning provider. Suppose the item for negotiation is the privacy of examination results. The employer would like to know how well the employee performed on a course in order to assign him appropriate tasks at work. Moreover, management (Bob, David and Suzanne) would like to share the results with management of other divisions, in case they could use the person's newly acquired skills. The negotiation dialogue can be expressed in terms of offers, counter-offers, and choices, as follows in Table 44.2 (read from left to right and down).

As shown in this example, negotiation is a process between two parties, wherein each party presents the other with offers and counter-offers until either an agreement is reached or no agreement is possible. Each party

15. G. Yee, and L. Korba, "Bilateral e-services negotiation under uncertainty," Proceedings, *The 2003 International Symposium on Applications and the Internet (SAINT 2003)*, Orlando, Jan 2003.
16. G. Yee, and L. Korba, "The negotiation of privacy policies in distance education," Proceedings, *14th IRMA International Conference*, Philadelphia, May 2003.

chooses to make a particular offer based on the value that the choice represents to that party. Each party chooses a particular offer because that offer represents the maximum value among the alternatives.

Each party in a negotiation shares a list of items to be negotiated. For each party and each item to be negotiated, there is a set of alternative positions with corresponding values. This set of alternatives is explored as new alternatives are considered at each step of the negotiation. Similarly, the values can change (or become apparent), based on these new alternatives and the other party's last offer.

Let R be the set of items r_i to be negotiated, $R = \{r_1, r_2, \ldots, r_n\}$. Let $A_{1,r,k}$ be the set of alternatives for party 1 and negotiation item r at step k, $k = 0,1,2,\ldots$, in the negotiation. $A_{1,r,0}$ is party 1's possible opening positions. Let $O_{1,r,k}$ be the alternative $a \in A_{1,r,k}$ that party 1 chooses to offer party 2 at step k. $O_{1,r,0}$ is party 1's chosen opening position. For example, for the first negotiation, the provider's opening position is *exam results can be seen by management*. Then for each alternative $a \in A_{1,r,k}, V_k(a)$ is the value function of alternative a for party 1 at step k, $k > 0$, and

$$V_k(a) = f(I, O_{1,r,k-1},\ O_{2,r,k-1}, \cdots)$$

where I is the common interest or purpose of the negotiation (e.g. negotiating privacy policy for "Psychology 101"), $O_{1,r,k-1}$ is the offer of party 1 at step k 2 1, $O_{2,r,k-1}$ is the offer of party 2 at step k 2 1, plus other factors which could include available alternatives, culture, sex, age, income level, and so on. These other factors are not required here, but their existence is without doubt since how an individual derives value can be very complex. Let $a_m \in A_{1,r,k}$ such that $V_k(a_m) = max\ \{V_k(a),\ a \in A_{1,r,k}\}$. Then at step k, $k > 0$ in the negotiation process, party 1 makes party 2 an offer $O_{1,r,k}$ where

$$O_{1,r,k} = a_m \quad if \quad V_k(a_m) > V_k(O_{2,r,k-1}), \qquad (1)$$

$$= O_{2,r,k-1} \quad if \quad V_k(a_m) \leq V_k(O_{2,r,k-1}). \qquad (2)$$

Equation 1 represents the case where party 1 makes a counter-offer to party 2's offer. Equation 2 represents the case where party 1 accepts party 2's offer and agreement is reached! A similar development can be done for party 2. Thus, there is a negotiation tree $\vec{r}$ corresponding to each item r to be negotiated, with two main branches extending from r at the root (see Figure 44.9). The two main branches correspond to the two negotiating parties. Each main branch has leaves representing the alternatives at each step. At each step, including the opening positions at step 0, each party's offer is visible to the other for comparison. As negotiation proceeds, each party does a traversal of its corresponding main branch. If the negotiation is successful, the traversals converge at the successful alternative (one of the parties adopts the other's offer as his own, Equation 2) and the negotiation tree is said to be complete. Each party may choose to terminate the negotiation if the party feels no progress is being made; the negotiation tree is then said to be *incomplete*.

In Figure 44.9, the influences arrows show that a particular alternative offered by the other party at step k will influence the alternatives of the first party at step $k + 1$. Figure 44.10 illustrates the negotiation tree using the above privacy of examination results negotiation.

Personal privacy policy negotiation may be used to avoid negative unexpected outcomes, even if the privacy policies involved are near well formed, since near well-formed policies may still not match. At a policies

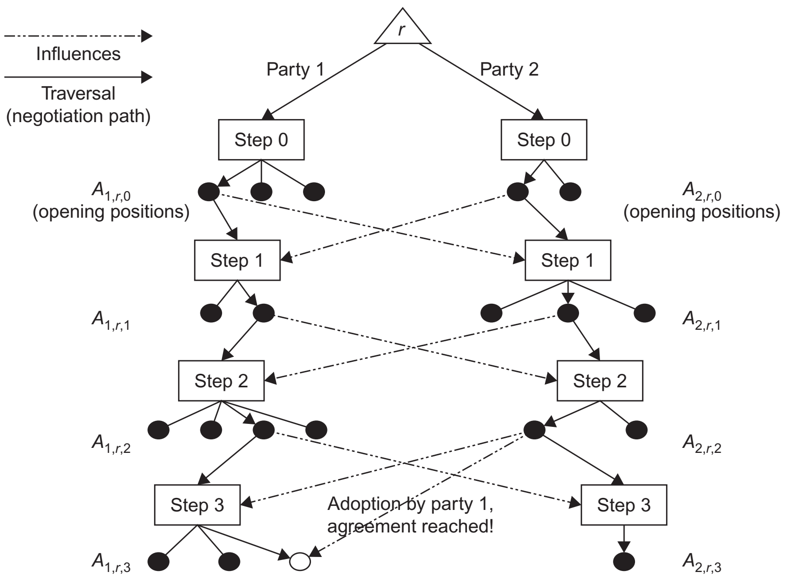

FIGURE 44.9 Negotiation tree $\vec{r}$ for a policy negotiation.

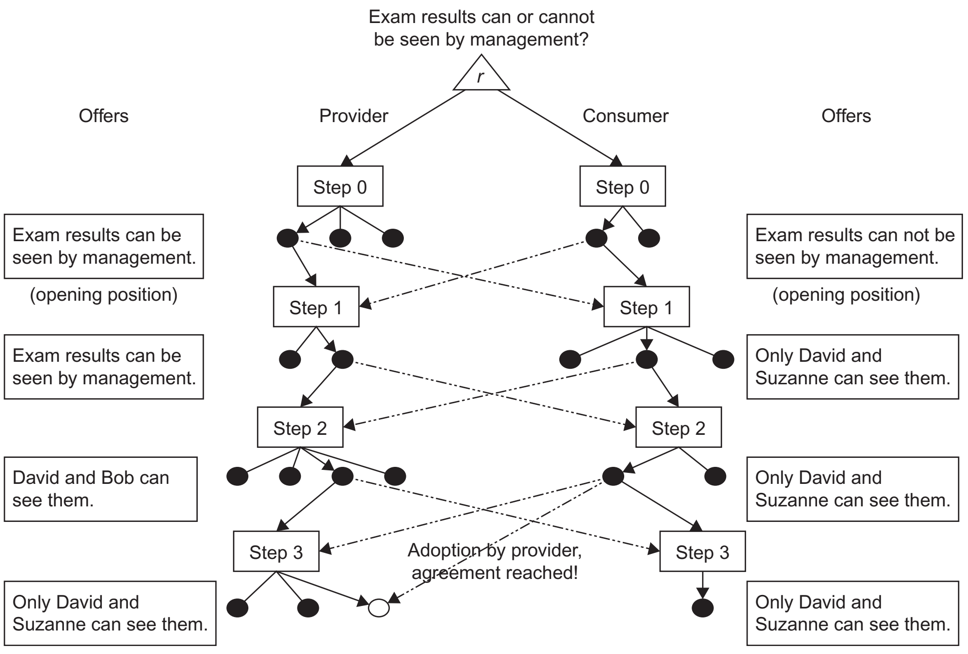

FIGURE 44.10 Negotiation tree for the first part of our negotiation.

mismatch, the consumer or the provider upgrades or downgrades the individual policy to try to get a match. In so doing, each could inadvertently introduce new values into the policy or remove values from the policy that result in negative unexpected outcomes or loss of NWF-ness. We propose the use of privacy policy negotiation between consumer and provider agents to guide the policy upgrading or downgrading to avoid undoing the values already put in place for NWF-ness in the initial specification. Alternatively, negotiation may expose a needed application of the above rules for a policy to be near well formed. This is also a consequences exploration, but here both provider and consumer do the exploration while negotiating in real time.

For example, in the All Books Online example of the "Outcomes From How the Matching Policy Was Obtained" section, where Alice does not need to provide her credit card, negotiation between Alice and All Books Online could have identified the consequence that Alice would need to wait longer for her order and direct her to another, more viable alternative, such as agreeing to provide her credit card. Similarly, in the example (same section) where the provider has to introduce more costly safeguards to protect the consumer's added highly sensitive information, negotiation could have uncovered the high sensitivity of the new information and possibly result in a different less costly alternative chosen (e.g., the new information may not be needed after all).

Table 44.3 illustrates how negotiation can detect and prevent the unexpected negative outcome of Alice having no access to medical service when it is needed (read from left to right and down). The result of this negotiation is that Nursing Online will be able to provide Alice with nursing service whenever Alice requires it, once she makes the change in her privacy policy reflecting the results of negotiation. If this negotiation had failed (Alice did not agree), Alice will at least be alerted to the possibility of a bad outcome, and may take other measures to avoid it. This example shows how negotiation may persuade the consumer to resolve a mismatch by applying the above rule for specifying *collector*.

Table 44.4 gives another example of negotiation at work using Alice's bookseller policy from Figure 44.1. This policy mismatched because Alice did not want to provide her credit-card information. At the end of the negotiation, Alice modifies her privacy policy and receives service from All Books Online.

Personal Privacy Policy Compliance

As we have seen, the above Privacy Principles require a provider to be accountable for complying with the Privacy Principles (CSAPP.1) and the privacy wishes of the consumer. In practice, a provider is required to appoint someone in its organization to be accountable for its compliance to Privacy Principles (CSAPP.1). This person is usually called the chief privacy officer (CPO). An important responsibility of the CPO is to put in place a procedure for receiving and responding to complaints or inquiries about the privacy policy and the practice of handling personal information. This procedure should be easily accessible and simple to use. The procedure should also refer to the dispute resolution process that the organization has adopted. Other responsibilities of the CPO

TABLE 44.3 Preventing Unexpected Negative Outcomes: Nursing Online.

Nursing Online (Provider)	Alice (Consumer)
Okay if a nurse on our staff is told your medical condition?	No, only Dr. Alexander Smith can be told my medical condition.
We cannot provide you with any nursing service unless we know your medical condition.	Okay, I'll see Dr. Smith instead.
You are putting yourself at risk. What if you need emergency medical help for your condition and Dr. Smith is not available?	You are right. Do you have any doctors on staff?
Yes, we always have doctors on call. Okay to allow them to know your medical condition?	That is acceptable. I will modify my privacy policy to share my medical condition with your doctors on call.

TABLE 44.4 Preventing Unexpected Negative Outcomes: All Books Online.

All Books Online (Provider)	Alice (Consumer)
Okay if you provide your credit-card information?	No, I do not want to risk my credit-card number getting stolen.
If you do not provide your credit-card information, you will need to send us a certified check before we can ship your order. This will delay your order for up to three weeks.	I still don't want to risk my credit-card number getting stolen.
Your credit-card information will be encrypted during transmission and we keep your information in secure storage once we receive it. You need not worry.	Okay, I will modify my privacy policy to share my credit-card information.

include auditing the current privacy practices of the organization, formulating the organization's privacy policy, and implementing and maintaining this policy. *We propose that the CPO's duties be extended to include auditing the provider's compliance to the consumer's personal privacy policy.*

Further discussion of personal privacy policy compliance is beyond the scope of this chapter. We mention in passing that an alternative method of ensuring compliance is the use of a Privacy Policy Compliance System (PPCS) as presented in.[17]

7. DISCUSSION AND RELATED WORK

We have presented methods for the semiautomatic derivation of personal privacy policies. Given our Privacy Management Model, there needs to be a way for consumers to derive their personal privacy policies easily or consumers will simply not use the approach. The only "alternative" that we can see to semiautomated derivation is for the consumer to create his/her personal privacy policy manually. This can be done by a knowledgeable and technically inclined consumer, but would require a substantially larger effort (and correspondingly less likely to be used) than the semiautomated approaches. In addition to ease of use, our approaches ensure consistency of privacy rules by community consensus. This has the added benefit of facilitating provider compliance, since it is undoubtedly easier for a provider to comply to privacy rules that reflect the community consensus than rules that only reflect the feelings of a few.

We believe our approaches for the semiautomatic derivation of personal privacy policies are quite feasible, even taking account of the possible weaknesses described in this chapter. In the surveys approach, the consumer has merely to select the privacy level when prompted for the rules from the provider's policy. In fact, the user is already familiar with the use of a privacy slider to set the privacy level for Internet browsers (e.g., Microsoft Internet Explorer, under Internet Options). We have implemented the surveys approach in a prototype that we created for negotiating privacy policies. We plan to conduct experiments with this implementation, using volunteers to confirm the usability of the surveys approach. In the retrieval approach, the consumer is asked to do a little bit more—compare and select the rules received—but

17. G. Yee, and L. Korba, "Privacy policy compliance for web services," Proceedings, *2004 IEEE International Conference on Web Services (ICWS 2004)*, San Diego, July 2004.

this should be no more complex than today's ecommerce transactions or the use of a word-processing program. Likewise, adapting a personal policy to a provider policy should be of the same level of complexity. Like anything else, the widespread use of these methods will take a little time to achieve, but people will come around to using them, just as they are using ecommerce; it is merely a matter of education and experience. Further, consumers are becoming more and more aware of their privacy rights as diverse jurisdictions enact privacy legislation to protect consumer privacy. In Canada, the Personal Information Protection and Electronic Documents Act has been in effect across all retail outlets since January 1, 2004, and consumers are reminded of their privacy rights every time they visit their optician, dentist, or other business requiring their private information.

We now discuss some possible weaknesses in our approaches. The surveys approach requires trust in the policy provider. Effectively, the policy provider becomes a trusted third party. Clearly, the notion of a trusted third party as a personal policy provider may be controversial to some. Any error made by the policy provider could affect PII for many hundreds or thousands of people. A certification process for the policy provider is probably required. For instance, in Canada, the offices for the provincial and federal privacy commissioners could be this certification body. They could also be policy providers themselves. Having privacy commissioners' offices take on the role of policy providers seems to be a natural fit, given their mandate as privacy watchdogs for the consumer. However, the process would have a cost. Costs could be recovered via micro-charges to the consumer, or the service provider for the policies provided. Aggregated information from the PII surveys could be sold to service providers who could use them to formulate privacy policies that are more acceptable to consumers.

There is a challenge in the retrieval approach regarding how to carry it out in a timely fashion. Efficient peer-to-peer search techniques will collect the rules in a timely manner, but the amount of information collected by the requester may be quite large. Furthermore, since the various rules collected will probably differ from one another, the requestor will have to compare them to determine which ones to select. Quick comparisons to reduce the amount of data collected could be done through a peer-to-peer rules search that employs a rules hash array containing hashed values for different portions of the rule.

In the section on policy compliance, a weakness of having the CPO be responsible for protecting consumer privacy is that the CPO belongs to the provider's organization. Will he be truly diligent about his task to protect the consumer's privacy? To get around this question, the CPO can use secure logs to answer any challenges doubting his organization's compliance. Secure logs automatically record all the organization's use of the consumer's private information, both during and after the data collection. Cryptographic techniques[18] provide assurance that any modification of the secure log is detectable. In addition, database technology such as Oracle9i can tag the data with its privacy policy to evaluate the policy every time data is accessed.[19] The system can be set up so that any policy violation can trigger a warning to the CPO.

An objection could be raised that our approaches are not general, having been based on privacy policy content that was derived from Canadian privacy legislation. We have several answers for this objection. First, as we pointed out, Canadian privacy legislation is representative of privacy legislation in many countries. Therefore the content of privacy policies derived from Canadian privacy legislation is applicable in many countries. Second, as we also pointed out, Canadian privacy legislation is also representative of the Fair Information Practices standards, which have universal applicability. Third, all privacy policies regardless of their content will have to converge on the content that we presented, since such content is required by legislation. Finally, our approaches can be customized to any form of privacy policy, regardless of the content. We next discuss related work.

The use of privacy policies as a means of safeguarding privacy for ebusiness is relatively new. There is relatively little research on the use of personal privacy policies. For these reasons, we have not been able to find many authors who have written on the derivation of personal privacy policies. Dreyer and Olivier[20] worked on generating and analyzing privacy policies for computer systems, to regulate private information flows within the system, rather than generating personal privacy policies. Brodie et al.[21] describe a privacy management workbench for use by organizations. Within this workbench are tools to allow organizational users tasked with the responsibility to author organizational privacy policies. The tools allow these users to use natural language for policy creation and to visualize the results to ensure that they accomplished their intended goals. These authors do not address the

creation of personal privacy policies. Irwin and Yu[22] present an approach for dynamically asking the user suitable questions to elicit the user's privacy preferences. They present a framework for determining which questions are suitable. However, there is no use of community consensus which means the resulting policies could be highly subjective. This means that providers would find it more difficult to use such policies to help them formulate provider privacy policies that would be acceptable to the majority of consumers.

Other work that uses privacy policies is primarily represented by the W3C Platform for Privacy Preferences.[23] This provides a Web site operator with a way of expressing the site's privacy policy using a P3P standard format and to have that policy automatically retrieved and interpreted by user agents (e.g., browser plug-in). The user can express rudimentary privacy preferences and have those preferences automatically checked against the web site's policy before proceeding. However, P3P cannot be used to fulfill the requirements of privacy legislation, has no compliance mechanism, and represents a "take it or leave it" view to privacy—if you don't like the privacy policy of the Web site, you leave it. There is no provision for negotiation. In addition, Jensen and Potts[24] evaluated the usability of 64 online privacy policies and the practice of posting them and determined that significant changes needed to be made to the practice in order to meet usability and regulatory requirements. Finally, Stufflebeam et al.[25] presented a case study in which they used P3P and Enterprise Privacy Authorization Language (EPAL) to formulate two healthcare Web site privacy policies and described the shortcomings they found with using these languages.

Negative outcomes arising from privacy policies may be regarded as a feature interaction problem, where policies "interact" and produce unexpected outcomes.[26] Traditionally, feature interactions have been considered mainly in the telephony or communication services domains.[27] More recent papers, however, have focused on other domains such as the Internet, multimedia systems, mobile systems,[28] and Internet personal appliances.[29] In this work, we have chosen not to frame negative outcomes from privacy policies as a feature interaction problem. In so doing, we have obtained new insights and results. Apart from feature interactions, other possible related work has to do with resolving conflicts in access control and mobile computing (e.g.[30,31]). However, it is believed that these methods and similar methods in other domains will not work for privacy due to the subjective nature of privacy, that is, personal involvement to consider each privacy rule is necessary.

Most negotiation research is on negotiation via autonomous software agents, focusing on methods or models for agent negotiation[32] and can incorporate techniques from other scientific areas such as game theory (e.g.[33]), fuzzy logic (e.g.[34]) and genetic algorithms (e.g.[35]). The research also extends to autonomous agent negotiation for specific application areas, such as ecommerce[36] and service-level agreements for the Internet.[37] Apart from

negotiation by autonomous software agents, research has also been carried out on support tools for negotiation (e.g.[38]), which typically provide support in position communication, voting, documentation communication, and big picture negotiation visualization and navigation.

8. SUMMARY

The protection of personal privacy is paramount if e-services are to be successful. A personal privacy policy approach to privacy protection seems best. However, for this approach to work, consumers must be able to derive their personal privacy policies easily. To describe semiautomated approaches to derive personal privacy policies, we first defined the content of a personal privacy policy using the Canadian Privacy Principles. We then presented two semiautomated approaches for obtaining the policies: one based on third-party surveys of consumer perceptions of privacy, the other based on retrieval from a peer community. Both approaches reflect the privacy sensitivities of the community, giving the consumer confidence that his/her privacy preferences are interpreted with the best information available. We then explained how personal privacy policies can lead to negative unexpected outcomes if not properly specified. We proposed specification rules that can be applied in conjunction with semiautomated policy derivation to result in near well-formed policies that can avoid the negative unexpected outcomes. We closed with our Privacy Management Model, which explains how privacy policies are used and the meaning of privacy policy matching. We described policy negotiation, not only for resolving policies that do not match, but also as an effective means for avoiding negative unexpected outcomes. Finally, we suggested how consumers could be assured that providers will comply with personal privacy policies.

We have based our work on our particular formulation of a privacy policy. An obvious question is whether our approaches apply to other formulations of privacy policies. We believe the answer is yes, for the following reasons: (1) privacy policy formulations (i.e., contents) cannot differ too much from one another since they must all conform to privacy legislation and our policy is a minimal policy that so conforms, and (2) if necessary, we can fit our approaches to any formulation by applying the same logic we used in this work.

Possible topics for future work include (1) looking at other methods for easily deriving personal privacy policies, (2) conducting experiments with volunteers, using the implementation of the surveys approach in our privacy policy negotiation prototype to confirm usability and resolve any scalability/performance issues, (3) investigating other possible unexpected outcomes from the interaction of privacy policies, (4) designing tools for outcomes exploration to identify the seriousness of each consequence, (5) exploring other methods for avoiding or mitigating negative unexpected outcomes from the interaction of privacy policies, and (6) investigating ways to facilitate personal privacy policy negotiation, such as improving trust, usability and response times.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The provider requires private information from the consumer for use in its e-service and so increases the consumer's privacy by requesting such information.
2. True or False? The Privacy Principles also prescribe certain operational requirements that must be satisfied between provider and consumer, such as identifying purpose and consent.
3. True or False? A semiautomated derivation of a personal privacy policy is the use of mechanisms (described in a moment) that may be semiautomated to obtain a set of privacy rules for a particular policy use.
4. True or False? The matching policy can be obtained through policy upgrades or downgrades.
5. True or False? Given that a provider always tries to reduce a consumer's privacy, it is possible that the policy nonmatch was due to the provider's policy requiring too much privacy reduction.

Multiple Choice

1. Since the consumer resists the provider's privacy reduction, it is possible that the __________ was due to the consumer's policy allowing too little privacy reduction.
   A. Privacy-enhancing technology
   B. Location technology
   C. Web-based
   D. Policy nonmatch
   E. Data controller
2. If the __________ field of the consumer's policy is not carefully specified, the provider may become

38. D. Druckman, R. Harris, and B. Ramberg, "Artificial computer-assisted international negotiation: a tool for research and practice," Proceedings of the *35th Annual Hawaii International Conference on System Sciences*, 2002.

confused upon expiry if there is not another consumer policy that becomes the new policy.

A. Information technology
B. Location technology
C. Valid
D. Privacy-enhancing Technologies
E. Web Technology

3. Specification of who is to collect the consumer's __________ needs to consider what happens if the collector is unavailable to receive the information.

A. Data minimization
B. *XACML*
C. Private information
D. Certification Authority
E. Security

4. Care must also be taken to specify the appropriate _________ for a particular information item.

A. Privacy metrics
B. Retention time
C. Privacy-Aware Access Control
D. Privacy preferences
E. Taps

5. If the __________ attribute of the consumer's privacy policy is not specified or improperly specified, providers can share the consumer's private information with other providers or consumers with resulting loss of privacy.

A. Release policies
B. Anonymous communication
C. Data handling policies
D. Disclose-to
E. Social engineering

EXERCISE

Problem

A medical office photocopied more of a car accident victim's record than necessary and released extremely sensitive but irrelevant information to the insurance company. Information about the woman's child, given up for adoption 40 years ago, eventually became part of the court record, a public document. What type of questions should you be asking with regards to this case?

Hands-on Projects

Project

An automobile dealer did not shred loan applications before tossing them into the garbage. A "dumpster diver" retrieved one and used the financial information to commit thousands of dollars of fraud against someone who had applied for a car loan. What type of questions should you be asking with regards to this case?

Case Projects

Problem

A medical doctor, who was filing for bankruptcy, faxed a financial document to his attorney. He entered the wrong telephone number, and the document was instead transmitted to the local newspaper. What type of questions should you be asking with regards to this case?

Optional Team Case Project

Problem

Five used copiers purchased from an office supply warehouse for about $400 each contained a gold mine of personal data. Using a forensic software program available free on the Internet, tens of thousands of documents were downloaded. Some of the data available included 106 pages of pay stubs with names, addresses and Social Security numbers; 400 pages of individual medical records; detailed domestic violence complaints and a list of wanted sex offenders; and a list of targets in a major drug raid. What type of questions should you be asking and comments made with regards to this case?

1. INTRODUCTION

The evolution of information systems is continuously increasing the capabilities and range of offered services, leading to infrastructures that see the participation of a larger number of users, a greater level of integration among separate systems, and a correspondingly larger impact of possible misbehaviors. Security solutions are available to protect the correct delivery of services, but these solutions have to adapt to the increasing complexity of system architectures. In this scenario, the management of security becomes a critical task. The goal is not only part of natural business practices, but it is also required to show compliance with respect to the many regulations promulgated by governments.

In modern information systems, a particular area of security requirement is access control management, with security policies that describe how resources and services should be protected. These policies offer a classification of the actions on the system that distinguishes them into authorized and forbidden, depending on a variety of parameters. Given the critical role of security and their large size and complexity, concerns arise about the policy's correctness. It is no longer possible to rely on the security designer to guarantee that the policy correctly represents how the system should protect access to resources.

Examples will be used to support the explanation and try to make the description self-contained. We want to provide an understanding of what we perceive as the main applications of these techniques.

The chapter is organized as follows. Section 2 introduces the concept of conflict in a security policy; then, the resolution of conflicts is discussed, and the relationship with separation of duty constraints is illustrated. Section 3 presents conflicts that arise in the execution of a security policy; the example of security policies for Java EE is used as an example. Section 4 offers an extensive analysis of conflict detection for network policies; significant attention is dedicated to this area, as it represents the domain where there is large experience in the use of conflict detection. Section 5 illustrates how Semantic Web technology can support the detection of conflicts in generic policies. Section 6 draws a few concluding remarks.

2. CONFLICTS IN SECURITY POLICIES

A typical top-down representation of the protection of an information system might consist of the five layers shown in Figure 45.1.

Security Requirements

Security requirements are a high-level, declarative representation of the rules according to which access control must be regulated. Security requirements largely ignore details of the system used to deliver the service, but focus on business concepts. This layer uses terminology and level of detail typical of the managers and are commonly expressed using natural language. For this reason, formal consistency verification cannot be automatically applied to the security requirements, and so human intervention will be required to complete the task.

Policies

Policies represent how business requirements are mapped to the systems used for service provisioning. Policies can

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00045-3

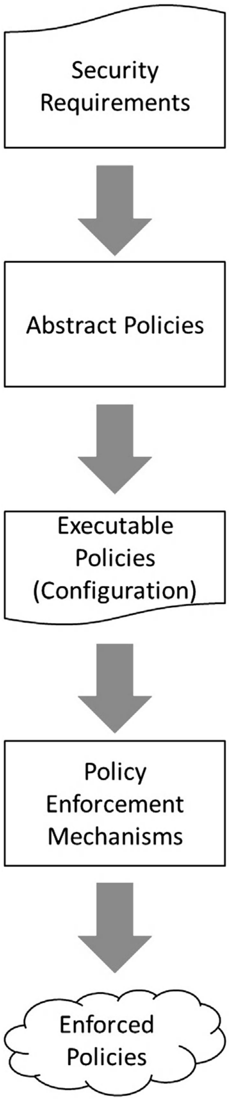

FIGURE 45.1 Top-down representation of the protection of an information system.

be defined at different levels, and the use of a higher level specification requires adopting an approach, possibly associated with a software tool, that supports the generation of lower level representations.

Abstract Policies

Abstract policies provide a formal representation of access control and its behavior. A policy may state, for instance, that an internal database storing credit-card information must not be accessible from the Internet. It is declarative because it does not detail the actual mechanism used for enforcing this policy. First, the policy is intended to define the desired behavior of the services. Since the policy will apply to abstract service definitions (services that are not yet instantiated), the specification cannot use full topological details.

Executable Policies

Executable policies describe the access control policy in a way that can immediately be processed by an access control component. Executable policies can be considered the security configuration of a system and are expressed in the specific language that a system recognizes. For instance, a policy for a relational Data Base Management System (DBMS) will typically be expressed by a sequence of Structured Query Language (SQL) statements.

Policy Enforcement Mechanisms

Policy enforcement mechanisms correspond to the low-level functions that implement the executable policies. It is convenient in the design and analysis of the system to separate the consideration of the policies (abstract and executable) from the mechanisms responsible for enforcing them, as each has its own weaknesses and threats.

Research has proposed multiple approaches for policy specification. Recent proposals have often been characterized by a direct integration with the languages and models of the modern Web scenario. These models include industry standards such as XACML [1], which is interesting because it can mostly be characterized as an abstract policy language, but it is also associated with tools that are able to directly process it, making it an executable policy. There are other abstract policy languages that a computer can directly process, such as rule-based policy notation using an if-then-else format, or proposals based on the representation of policies using Deontic logic for obligation and permissibility rules. Academic efforts produced solutions ranging from theoretical languages like the one proposed by Jajodia et al. in [2] to executable policy languages such as Ponder [3]. In the Semantic Web area have emerged proposals such as Rei [4] and KAoS [5]. Policy languages based on Semantic Web technologies allow policies to be described over heterogeneous domain data and promote a common understanding among participants, who might not use the same information model.

A crucial advantage of using a formal policy representation, particularly at the abstract level, is the possibility of an early identification of anomalies. Security policies in real systems often exhibit contradictions (inconsistencies in the policy that can lead to an incorrect realization of the security requirements) and redundancies (elements of the policy that are dominated by other elements, increasing the cost of security management without providing benefits to the users or applications). The availability of a high-level and complete representation of the security policies supports the construction of services for the analysis of the policies able to identify these anomalies and possibly suggest corrections. A classical taxonomy of conflicts is shown in Figure 45.2.

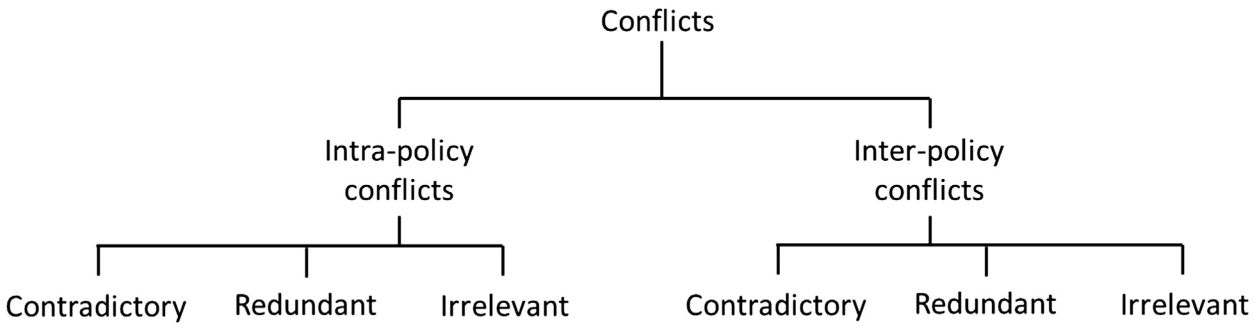

FIGURE 45.2 Taxonomy of conflicts.

#	Sign	User	Action	Resource
1	+	Alice	read	file1
2	+	Bob	write	file2
3	-	Alice	read	file1
4	+	Bob	write	folder (contains file1 and file2)

FIGURE 45.3 Examples of contradictory and redundant conflicts.

As depicted in Figure 45.2, conflicts can be divided into two categories: (a) *intra-policy* conflicts that may exist within a single policy and (b) *inter-policy* conflicts that may exist between at least two policies. For each category we have the following subcategories: (a) contradictory, (b) redundant, and (c) irrelevant.

Contradictory

Contradictory conflicts arise when principals are authorized to do an action a on a resource r by a positive authorization, and are forbidden to do the same action a on the resource r by a negative authorization. In this case, the two authorizations are said to be incompatible. For example, in Figure 45.3 authorization 1 is in conflict with authorization 3. In fact, authorization 1 states that Alice can read file1, and authorization 3 states that Alice cannot read file1.

Contradictory authorizations make the policy inconsistent. The security administrator has to be alerted, to correct this error by editing or removing the conflict. In network policies, a classification is introduced that further refines this type of conflict.

Redundant

Redundant conflicts arise when an authorization is dominated by other authorizations and does not contribute to the policy (its removal would not modify the behavior of the system). Given two authorizations a_1 and a_2 with the same action and sign, let us call p_i (respectively, r_i) the principals (respectively, resources) associated, directly or indirectly, with a_i. If $p_2 \subseteq p_1$ and $r_2 \subseteq r_1$ and a_2 is not involved in any conflict with other authorizations, then a_2 is redundant with respect to a_1, and can be safely removed from the policy without modifying the behavior of the system. For example, in Figure 45.3 authorization 2 is redundant with respect to authorization 4 because authorization 4 dominates (it is expressed on the folder) authorization 2 (it is expressed on file1, but it is contained in the folder).

Irrelevant

Irrelevant conflicts occur when the conflict can never manifest itself in a system. This may happen when the specification of the elements of the authorizations cannot lead to activation of all the authorizations involved in the conflict. Recognizing that a conflict is irrelevant may be hard, depending on the expressive power of the language used for representation of authorizations. Examples are presented in Section 4 when discussing conflicts in network policies.

This classification is a starting point for evaluation of the conflicts. In the next section we present some examples of conflicts and discuss the introduction of techniques for resolution of conflicts, able to solve contradictions in the policy.

Conflict Resolution

Security policies in real systems often exhibit conflicts and redundancies. The availability of a high-level and complete representation of the security policies supports the construction of services for the analysis of the policies able to identify these anomalies and possibly suggest corrections. Contradictions in the policy are also called *modality conflicts*. They arise when principals are authorized to do an action a on a resource r by a positive

authorization, and forbidden to do the same action *a* on resource *r* by a negative authorization.

In this case, the two authorizations are said to be *incompatible*. An example has been presented before, with authorization 1 and authorization 3 in Figure 45.3.

In the literature and in systems, several criteria have been proposed and implemented to manage at policy execution time this kind of conflict [6], aiming at removing the ambiguity in the policy and solving the conflict. Consider, in that regard, the case of a generic network firewall device, whereby packet filtering rules are evaluated in a given order and, as such, any conflict among them (more than one rule matching to the same packet) is deterministically solved by evaluating the result dictated by the first matching rule. The rules that handle the composition of authorizations in order to solve the conflicts do not necessarily have to be fixed. More sophisticated languages are in fact equipped with specific constructs to instruct the policy evaluator to apply one out of several possible composition strategies. The XACML language [1], for instance, defines so-called combining algorithms to compose the results of different access control rules. Examples of the available options are the "*deny-overrides*" algorithm, where rules prescribing access denial take precedence. This means that in case of conflict, the negative authorization always wins, so a forbidden action will never be permitted. For the example presented in Figure 45.3, this means that authorization 3, being negative for subject Alice, has priority over authorization 1, so Alice is not allowed to read file1. Another strategy that sees extensive adoption in operating systems is the "*first-applicable*" one, where rules are evaluated in order, such as in the aforementioned case of a network firewall. In a similar fashion, the Apache Web server access control configuration language permits specification of the order of priority of rule evaluation: For example, the "Order allow, deny" directive determines the priority of permissions over denials.

Other important criteria are those based on identification of a dominance relationship among rules. This is represented by the criterion "*most specific wins*," which states that, when one authorization dominates the other, the more specific wins. In most cases this represents an adequate and flexible solution. A critical problem of this approach is that specificity may not always be defined for conflicting authorizations, for a variety of reasons.

A first case is represented by the authorizations supporting a hierarchy for any element of the (<*subject, action, resource*>) triple, with the possibility to be contained in more than one ancestor. For example, for a given action and resource, authorization *A3* has a positive sign and is applied to group *G1*, and authorization *A4* has a negative sign and is applied to group *G2*, with *G1* and *G2* not contained one into the other and with a user *u* belonging to both groups. In this situation, the "*most specific wins*" does not solve the conflict. A second case occurs when containment hierarchies are possible on more than one element. For example, authorization A5 has a positive sign and applies to user *u* when accessing elements in the resource group RG; authorization *A6* has a negative sign and applies to user group *UG* when accessing element *r*; if *u* is a member of *UG* and *r* is included in *RG*, the "*most specific wins*" criterion is not able to manage the conflict. Other solutions have been proposed that rely on the explicit specification of a priority for each authorization. If a partial order is specified, using the same priority for sets of authorizations, the possibility of unresolved conflicts remains. If priorities build a total order on authorizations, conflicts would be solved, but it appears quite difficult to assign in an efficient way priorities that are consistent with the application semantics.

An option that can solve all the conflicts is to combine multiple resolution criteria, applying each one only after the previous ones were not able to solve the conflict. For instance, the "*most specific wins*" can be applied first, and the "*deny overrides*" can be used to solve the remaining conflicts. This is in most cases a solution preferable to identification of some fixed ordering of the authorization that is not consistent with the semantics of the policy. Another option that has a significant potential, particularly when dealing with abstract policies that will be mapped to executable policies, is to use the "*most specific wins*" criterion as a first step, and let the conflict detection solutions notify the security administrator of the remaining conflicts, in order to either modify the policy or introduce an ad-hoc solution. Support for this approach can be offered by use of Semantic Web tools, as discussed in Section 5.

Separation of Duty

The conflicts presented until now derive from the presence of positive and negative authorizations in the same policy that can be applied to the same access request. A different kind of conflict derives from the definition in the security policy of constraints that the authorizations have to satisfy. An important class of constraints is *Separation of Duty* (*SoD*). These constraints follow the common best practice for which sensitive combinations of permissions should not be held by the same individual, in order to avoid the violation of business rules. The purpose of this constraint is to discourage fraud by spreading the responsibility and authority for an action or task, thereby raising the risk involved in committing a fraudulent act, by requiring the involvement of more than one individual. The idea of Separation of Duty long existed before the information age and is extensively used in some areas, like the bank industry and the military.

Role-Based Access Control can be adapted to express this kind of constraint because the role hierarchy allows an easy mapping of real-world business rules to the access control model.

A well-known example is the process of creating and approving purchase orders. If a single person creates and approves purchase orders, it is easy and tempting for them to create and approve a phony order and pocket the money. If different people must create and approve orders, then committing fraud requires a conspiracy of at least two people, which significantly lowers the risk.

The two main categories of Separation of Duty are (a) Static Separation of Duty (*SSoD*) and (b) Dynamic Separation of Duty (*DSoD*) (see Figure 45.4). The former category (also known as strong exclusion) is the simplest way to implement SoD. Given two roles $role_1$ and $role_2$, the Static SoD between these two roles means that a user u must not exist who can activate both $role_1$ and $role_2$. For instance, if *Order Creator* and *Order Approver* are strongly exclusive roles, then no one who may assume the Order Creator role would be allowed to assume the Order Approver role, and vice versa no one who may assume the *Order Approver* role would be allowed to assume the *Order Creator* role.

The latter category (also known as weak exclusion) states that "A principal may be a member of any two exclusive roles, but he must not activate both at the same time." This definition implies that the system will keep precise track of each task. Before doing any task, the system will check that the separation of duty is not violated. Dynamic separation of duty allows the users to perform the roles that would be strongly exclusive in static systems.

Violations of the Separation of Duty constraints policy are another kind of conflict. Support for this conflict can be adequately provided by the implementation of conflict detection services, which are able to notify the security designer of inconsistencies in the policy. Resolution of such a conflict will typically require either revising the policy, restricting the user's ability to enact conflicting roles, or modifying the specification of the constraint. The efficient identification of these violations can use ad-hoc solutions. An interesting option is represented by the use of Semantic Web tools, as discussed in Section 5.

3. CONFLICTS IN EXECUTABLE SECURITY POLICIES

We have so far focused on how conflicts have been studied in the context of abstract security policies, where the specific details on the implementation of the policy enforcement mechanisms are not part of the model. Therefore they are not assumed to possibly introduce any issue in the policy evaluation.

In this section we instead consider the case of concrete policy evaluation frameworks, where an *evaluation algorithm* determines the effect of a given policy according to:

- An executable representation of the policy
- Context-dependent information

The executable policy can be seen as the configuration of the security enforcement mechanism, and it can be referred to as its *security configuration*. A security configuration is typically expressed according to a respective *configuration language*. The semantics of this language is ultimately given by the evaluation algorithm that computes the result of a configuration at operations time. As a consequence, configuration authors need to have a thorough understanding of the semantics evaluation, such that they can configure the behavior of the enforcing mechanism exactly according to the policy they want the system to implement.

Security configuration languages and corresponding evaluation semantics typically incorporate mechanisms to cope with conflicts that may arise at the evaluation stage. This can be achieved, on the one hand, by constraining the expressiveness of the configuration language so that

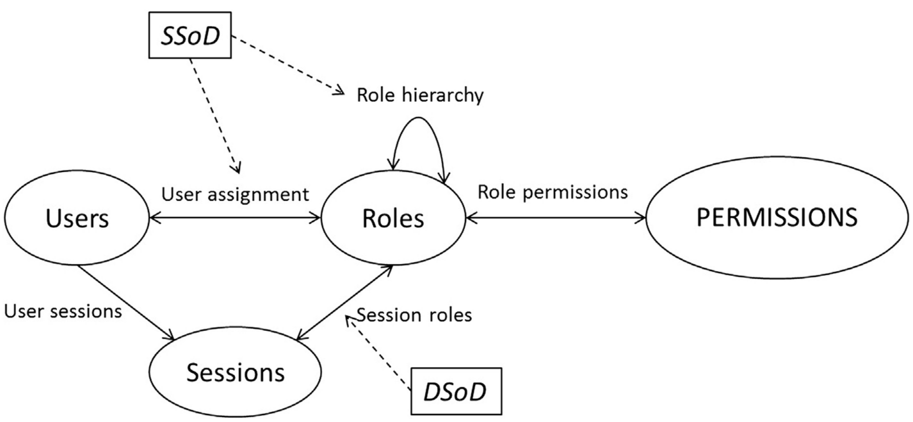

FIGURE 45.4 NIST RBAC model.

some inconsistencies are syntactically ruled out; for instance, contradictions in the policy (cf. Section 2) cannot occur in the case of an access control configuration language that only allows specifying collections of positive (respectively, negative) authorization rules. On the other hand, solutions to resolve the conflicting situations can be included in the evaluation semantics. For example, the rules that determine the semantics of the composition of different constructs of the language can be designed to handle conflicts by applying a predetermined strategy, as discussed earlier.

Although policy conflicts are sorted out in the evaluation semantics of security configuration languages, errors can still be introduced by inexperienced configuration authors. As a matter of fact, the gap of abstraction that lies between a security configuration and the corresponding enforced abstract policy is not dissimilar to the difference between a program's source code and the behavior realized by an interpreter while executing the program (cf. Figure 45.5). As such, policies that enforce unintended security properties can stem from misconfigured security enforcement devices, like bugs in the program's source code produce an incorrect runtime behavior.

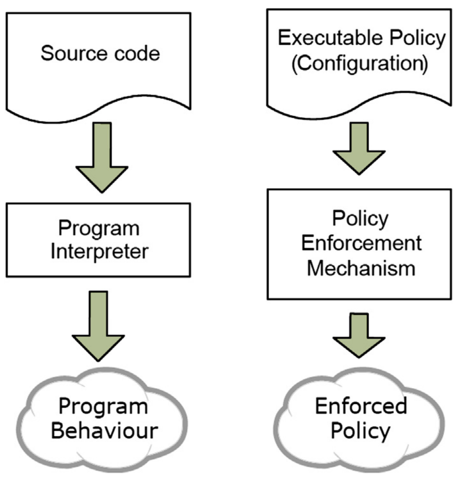

FIGURE 45.5 Analogy between program interpretation and the low portion of Figure 45.1.

To solve this issue, researchers have been studying the characteristics of security policy languages and their semantics in order to:

- Identify in particular counterintuitive corner-cases or anomalous situations that likely stem from misconfigurations.
- Propose models to automatically detect and possibly solve such misconfigurations.

In the following we discuss these issues in the scenario of Java Enterprise Edition. The treatment will also use some concrete examples of the security configuration language.

Java EE Access Control

The Java Enterprise Edition (Java EE) platform consists in a set of API and a runtime environment that allow development and execution of distributed Web-based applications. The basic execution model of a Java EE Web application is depicted in Figure 45.6. HTTP requests coming over the network are processed by the Java EE application server and abstracted to *HttpServlet Request* Java objects, which constitute the input of the Web application. Web applications are composed of *Web Components*, dealing with the client's requests and computing responses, and *JavaBeans Components* which can be optionally involved to encapsulate the business logic of large-scale Web applications.

The interface between the Web Components and the application server, providing their execution environment, is standardized in the Java EE Servlet Specification [7]. This document establishes a contract between application server implementations on one side and Web applications on the other, prescribing, among others, a number of mechanisms to deal with security in Java EE Web applications.

Such mechanisms belong to two categories: programmatic security and declarative security. Programmatic security describes functionalities that developers can use through an API to implement security within their application's code. Declarative security refers instead to the enforcement of security properties (such as HTTP-based

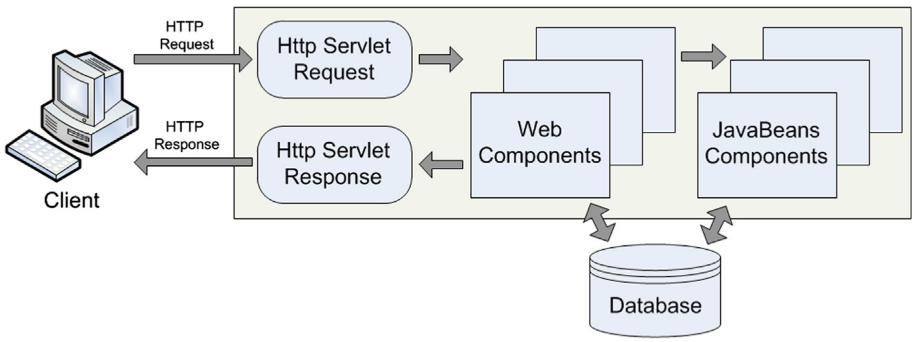

FIGURE 45.6 Execution model of a Java EE Web application [7].

access control) achieved not through dedicated source code in the application, but rather through the declarative specification of security configurations. In the latter case, the enforcement of security at runtime is completely transparent to the Web application's developer. When the Web application is deployed within the application server, it comes together with a configuration file, the so-called deployment descriptor, where security and several other aspects of the Web application's runtime environment are configured. Analogous mechanisms are likewise available for JavaBeans Components, as described in a dedicated specification [8].

As we are interested in discussing examples of security configuration languages, in this section we focus on declarative security. We first provide an overview about its evaluation semantics and then examine different approaches to the analysis of Java EE security configurations.

The deployment descriptor of Web Components is a XML document that conforms to a grammar (XML schema) defined as part of the Servlet Specification. The security-related fragment of this grammar is the subtree rooted at the *security constraint* XML tag.

Every security constraint associates a set of resources (i.e., URLs of the Web application) with the required security properties. Two categories of security properties can be configured: *authorization constraints*, which are access control on URLs, and *user data constraints*, which stand for confidentiality or integrity requirements on data exchanged between the client and the Web application. Access control is configured by associating URL patterns and a (possibly empty) set of HTTP methods to at most one authorization constraint, that is, the set of roles allowed to access the mentioned resources. Wildcards are allowed in the definition of both URL patterns and granted roles: in particular (i) the special role name '*' is shorthand for all the roles defined inside the deployment descriptor, and (ii) entire URL hierarchies can be specified with URL patterns ending with the '/*' wildcard.

Similarly, requirements on data confidentiality or integrity are specified by associating URL patterns and HTTP methods with one or more transport guarantee XML nodes, containing either the CONFIDENTIAL or INTEGRAL keywords.

According to the informal semantics from [9], in order to have access granted, a user must be a member of *at least one of the roles* named in the security constraint (or implied by '*') that matches her/his HTTP request. An empty authorization constraint means that *nobody* can access the resources, whereas access is granted to *any* (possibly unauthenticated) user in case the authorization constraint is omitted. Unauthenticated access is also allowed by default to any unconstrained resources. It's worth noting that an intuitively insignificant syntactic difference, such as omitting the authorization constraint instead of specifying an empty one, corresponds to a major gap in semantics, respectively, *allow all* or *deny all* behaviors are obtained.

In case the same URL pattern and HTTP method occur in different security constraints, they have to be conceptually composed, as they apply to overlapping sets of resources. For what concerns access control, if two nonempty authorization constraints are composed, the result is the *union* of the two sets of allowed roles. If one of the two allows unauthenticated access, the composition also does. In contrast, if one of the sets of roles is empty, their composition is empty; that is, the *intersection* of the two sets is performed in this case. Constraints on more specific URL patterns (*/a/b*) always override more general ones (*/a/**). The composition of user data constraints, instead, is always the union of the single requirements.

The following snippet is an example of two overlapping security constraints. As a result of their composition, no access is granted to the URL hierarchies '*' and '*/acme/wholesale/**' via the *DELETE* and *PUT HTTP* methods. Access to '*/acme/wholesale/**' via *GET* is restricted to users having the role *SALESCLERK*. HTTP requests with any method other than the aforementioned are instead granted to anyone:

```
<security-contraint>
<web-resource-collection>
<url-pattern>/*</url-pattern>
<url-pattern>/acme/wholesale/*</url-
pattern>
<http-method>DELETE</http-method>
<http-method>PUT</http-method>
</web-resource-collection>
<auth-constraint/>
</security-contraint>
<security-contraint>
<web-resource-collection>
<url-pattern>/acme/wholesale/*</url-
pattern>
<http-method>GET</http-method>
<http-method>PUT</http-method>
</web-resource-collection>
<auth-constraint>SALESCLERK</auth-
constraint>
</security-contraint>
```

It is suggested [10] that the evaluation semantics of security constraints for Java EE Web Components is partly counterintuitive, specifically in its fragments concerning composition, which is where, as argued earlier, the rules to deal with conflicts are encoded. The peculiar handling of unconstrained HTTP methods and the fact that more specific URL patterns shall override less specific ones, for instance, may lead to unexpected behaviors, as illustrated in the following example.

Let us consider again a couple of security constraints introduced above. According to the aforementioned interpretation, the *HTTP DELETE* requests to the URL */acme* are denied, as the first constraint applies. In contrast, requests to the same URL but through any unconstrained method, such as *GET*, are allowed to anyone.

We now assume that a system administrator, wanting to deny *GET* requests to the URL */acme*, added the following constraint:

```
<security-contraint>
<web-resource-collection>
<url-pattern>/acme</url-pattern>
<http-method>GET</http-method>
</web-resource-collection>
<auth-constraint/>
</security-contraint>
```

Since this new constraint is the most specific for the URL */acme*, and it does not specify any behavior for methods other that *GET*, it introduces a side effect by allowing requests that were previously denied. For example, the *DELETE* requests to */acme* become *allowed to anyone*, after introducing this constraint. This behavior is particularly counterintuitive because the new constraint does not include any reference to the *DELETE* method, which is nevertheless affected. Also, although apparently it specifies *access denial* (empty authorization constraint), it implicitly carries *access permission* semantics for every unconstrained method.

The authors of [10] argue for the need of a formal characterization of the semantics of security constraints, which can be used as a reference to check the correctness of the behavior of both application server implementations and Web application configurations. Hence, they propose a set-theoretic model that captures the expressiveness of Java EE Web Components' authorization constraints, where resources form a set ordered according to the URL tree hierarchy and sets of roles, ordered by inclusion, form a lattice of permissions.

4. CONFLICTS IN NETWORK SECURITY POLICIES

The identification of conflicts in security policies has been particularly investigated in the scenario of the configuration of computer networks. This area of security sees a significant industrial interest, is today one of the most critical components in the protection of an information system from external threats, and relies on a protection model that is well understood and adequate to the realization of a number of ad-hoc solutions. We consider it interesting then to analyze the solutions that have been devised for detection of policy conflicts in this scenario. The analysis will give a more precise understanding of the problems that can be faced when managing conflicts in a real system, and the results of the work in this area provide important guidelines that can drive the design of this functionality in the different scenarios where security policies are defined. First, we will consider the configuration of firewalls. Then, we will analyze how the configuration of channel protection solutions can identify other kinds of conflicts in the policy.

Filtering Intra-policy Conflicts

Firewalls are devices used to separate parts of networks parts that have different security levels; in fact, they are able to enforce an authorization policy that selects the traffic to be allowed according to a security policy expressed as a set rules, often named the access control list (ACL). The rules are composed by a *condition* clause, formed by a series of predicates over some packet header fields, and an action clause, determining the action to be enforced, typically allowing or denying the traffic.

When a new packet arrives at one of the firewall network interfaces, the values from its headers are used to evaluate the condition clause predicates [10,11]. A packet matches a rule if all the predicates of the rule are true. If a packet matches only one rule, the action enforced is taken of its action clause. However, in an ACL, a packet can match more than one rule; therefore rules are prioritized and the action from the matching rule at the highest priority is enforced. This approach is often named the "*first applicable*" resolution strategy, based on ordering rules by priority and starting from the highest priority one; the action enforced is the one from the first matching rule. However, hardware-based approaches use ad-hoc algorithms and fast memories that speed up the matching process considerably. In practice, the ACL is not scanned linearly, as the action is selected by fast look-up algorithms [12]. It also may happen that a packet does not match any of the ACL rules.In that case, a default action is enforced; typically, the traffic is denied and the packet is dropped.

Firewalls are categorized according to their capabilities or the layer at which they work (that is, the headers they can consider). The simplest firewall capability is the *packet filter*, working at the network and transport ISO/OSI layer, that takes decisions based on five fields: IP address and ports of the source and destination, and the IP protocol type. Packet filters do not maintain state information (distinguishing packets that belong to an established TCP connection), and they are also referred to as *stateless firewalls*.

A firewall that performs the stateful packet inspection is named a *stateful firewall*, and it usually maintains information about the TCP state, but also about other stateless protocols (ICMP echo-request echo-reply sequences) or

stateful application-layer protocols (understanding the opening of FTP data ports in active or passive mode). At the highest level of the ISO/OSI stack, there are the *application firewalls*. Because application protocols are very heterogeneous, application firewalls are usually tailored to one or more specific protocols to perform a more focused analysis. The most widespread one is the Web Application Firewall (WAF), which observes HTTP properties and fields, including MIME objects, and, if integrated with the Web service it protects, can also circumvent common attacks and vulnerability exploits. Additionally, application firewalls are able to check the "RFC compliance" that verifies whether the protocol traffic is consistent with the standards or with a set of nonharmful implementations. Therefore, the condition clause of stateful and application firewalls also contains predicates over state information and application protocol fields.

Condition clauses are not just modeled as logical predicates; in fact, many works represent them as using geometrical models that are proven equivalent. Ac- cording to the geometric view, every packet is a point in a decision space, composed by many dimensions, one for each field for which it is possible to state a condition. A rule thus becomes a hyper-rectangle. For instance, the decision space of packet filters is often named five-tuple space. A packet matches a rule if it is in the rule hyperrectangular area. For instance, a simple bidimensional case is represented in Figure 45.7.

As firewalls are a major security shield against attacks and intrusions, their correct configuration has always worried administrators. However, most firewalls are very poorly configured, as Wool highlighted in a study in 2004 whose trend was recently confirmed [13,14]. Historically, three approaches are used to verify the correctness of intra-firewall policies: manual testing, query-based approaches, and use of conflict and anomaly analysis tools. Recently, companies have been using complex distributed systems with many firewalls and redundant controls; therefore, all these approaches have been designed or extended to the inter-firewall policies analysis.

In the inter-firewall policy analysis, verification of the correctness of the action enforced by a firewall is extended to a more general case, evaluating the actual reachability by analyzing the actions enforced by all the firewalls encountered in a communication path.

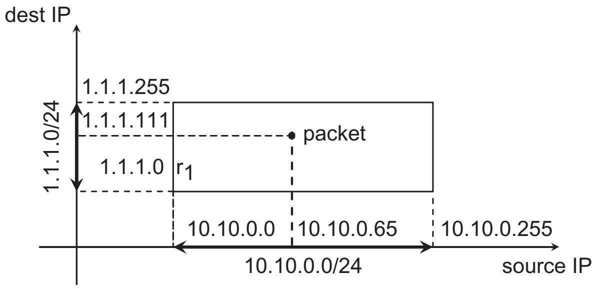

FIGURE 45.7 Geometric representation of a rule and a packet.

Manual Testing

Manual testing is the first and the simplest case. It can be performed by actually trying a set of connections to verify if they succeed and comparing them with the authorization policy, or using software able to probe hosts, servers, and other devices for open ports and available features, that is, the vulnerability scanner. Many scanners are available to this purpose, mostly as open-source software, like nmap [15], Amap [16], and Nessus [17]. They are sophisticated and can be used to detect more complex cases (to recognize OS and software fingerprints, or to distinguish filtered ports from closed ones) or to identify known vulnerabilities. This approach is very time consuming and requires an effort that, especially in large networks, is beyond the administrator's possibilities. Additionally, it requires actual deployment of the policy and physical access to the network, which may also be flooded by probe packets that may interfere with normal network functioning. Although scanners' output is very detailed, they need a further step to be compared with the firewall policy and to actually know if it has been correctly implemented.

5. QUERY-BASED CONFLICT DETECTION

The first attempts to overcome the limitations of the manual approach consisted in representing a firewall policy using an abstract format in order to perform queries and figure out the actual firewall behavior, by evaluating the action it would enforce instead of actually trying the connections. Firewall queries can be considered as questions concerning firewall behavior [16]. Examples of questions of interest to administrators are: "Which clients can access the server s1?", or "Which server is reachable from the Internet?" This query-based approach easily extends to the analysis of firewalls in distributed systems. In fact, the firewall questions can be easily extended to more general reachability problems.

Querying a firewall requires an abstract representation of the policy it implements and an abstract representation of the issued question. One major theoretical problem is the query aggregation. In fact, the number of cases to be considered, for instance, to answer the previous questions, is too large: For a five-tuple IPv4 packet filter there are 2^{104} different packets, potentially corresponding to cases to consider.[1] It is critical to use IP address ranges instead of single addresses and port intervals, merging adjacent

1. 32 bits for source and destination IPv4 addresses, 16 bits for ports, and 8 for the protocol type.

intervals. The aggregation of the results is also complex and computationally expensive, as the union of rectangles is not always a rectangle.

The first tool produced was Fang [18], a simulation-based engine that performs simple query aggregation. Its successor, Firewall Analyzer (formerly known as Lumeta) [19,20], also provided standard queries and import functionalities to automate the analysis and to facilitate the job of the administrators. Another early work from Hazelhurst [21] concentrated on a simple query-based analysis.

Recently, Liu proposed the Structured Firewall Query Language (SFQL) and an associated intra-firewall query engine [22], which he extended to analysis of corporate networks composed of packet filters also having network address and port translation capabilities (NAT and NAPT) [11]. SFQL is a SQL-like language that permits specifying queries in a compact and familiar syntax. Assuming that D is the field name for the destination address, S for source address, N for the destination port, and P for the protocol type, the following query answers the following question: "Which are the IP (source) addresses of computers that can reach the web service s_1 available at 10.0.0.1:80/TCP?" Please see the following lines of code:

```
Select S
from firewall
where {S ∈ all} ∧
{D ∈ 10.0.0.1} ∧
{N ∈ {80}} ∧
{P ∈ {TCP}} ∧
{decision = accept}
```

The main limitation of the firewall querying approach is that the questions to issue are selected by administrators who have to identify the meaningful queries, write them correctly, aggregating if needed the results of more queries (similarly to the SQL union clause), and analyze the results which may be very large. However, they "often do not know what to query" [18]. In literature, only the Firewall Analyzer addressed this problem, proposing a set of standard queries.

Conflict Detection by Anomaly Classification

A different method to identify whether the firewall policy is correct consists in performing an exhaustive analysis of the access control list (ACL), to detect all the situations that may be evidence of a misconfiguration. Even though the terms *conflict* and *anomaly* are often used synonymously, in this field they have different meanings: a *conflict* is an occurrence that may stop the correct working (having two matching rules in a router that only allows for one matching rule at the time); an *anomaly* is a particular relation between one or more ACL rules that administrators have to consider, as it may be the evidence of specification mistakes, but that is perfectly allowed by the examined control.

Sloman [23–25] initially introduced the concept of conflicting policy, but the methods he presents are not directly applicable to firewall policies and in general to all the low-level configurations. Many seminal papers present solutions for analysis of packet filtering. First works concentrated on efficient representations of the ACL, as conflicting rules decrease performance or were not allowed in devices, due to the limited computation capabilities.

The approaches are mainly equivalent, even if they use different rule representations. Hazelhurst presented solutions based on binary decision diagrams (BDDs) [21], Hari [26] proposed the use of tries, Baboescu [27] the use of bit vectors, and Srinivasan [28] the Tuple Space Search classification algorithm.

The first formalization of the anomaly concept has been proposed by Al- Shaer who focused on the intra-policy analysis of packet filters [10]. He introduced the concept of anomaly, defined as "the existence of two or more filtering rules that may match the same packet, or the existence of a rule that can never match any packet" and identified five rule-pair anomaly types: *shadowing*, *correlation*, *generalization*, and *irrelevance* and presented an algorithm to discover and manage anomalies in ordered rule lists. Given two rules r_1 and r_2 where r_1 is the highest priority rule, the rule-pair anomalies are:

1. *Shadowing anomaly*: r_2 is shadowed when r_1 matches all the packets that r_2 matches, so that r_2 will never be activated (see Figure 45.9b);
2. *Correlation anomaly*: r_1 and r_2 are correlated if (1) they enforce different ac- tions and (2) there exists some packet matching both r_1 and r_2 and (3) there exists some packet matching r_1 but not r_2 and vice versa (see Figure 45.8b);
3. *Generalization anomaly*[2] : r_2 is a generalization of r_1 if (1) they enforce dif- ferent actions and (2) all the packets matching r_1 also match r_2, but not the contrary (see Figure 45.8c);
4. *Redundancy anomaly*: r_2 is redundant if r_1 matches the same packets and enforces the same action as r_2, so the removal of r_2 will not change the policy behavior (see Figure 45.9a);
5. *Irrelevance anomaly*: A rule is irrelevant if does not match any packet that could pass through the firewall. It does not concern relations between rules, but rather between a rule and the enforcing device.

2. In [29] this is named exception.

For instance, with reference to Table 45.1, r_1 is a generalization of r_2, r_2 shadows r_3, makes r_4 redundant, and is correlated to r_5. Finally, r_6 is irrelevant if the traffic from IP address 5.5.5.5 cannot reach the firewall interfaces.

Al-Shaer's classification has a limitation because it detects only anomalies in rule pairs; anomalies that arise when more rules are considered are not discussed. Basile [29,30] generalized Al-Shaer's classification to multi-rule anomalies, that is, anomalies that involve more than two rules. The firewall policies are categorized as *conflicting* when at least two rules contradict each other (that includes the correlation, generalization and shadowing anomalies), and suboptimal when the removal of one or more rules does not affect the behavior of the firewall (that includes shadowing and redundancy). Suboptimality is caused by *hidden rules* (rules that are never activated, regardless of the number of rules that hide them). Hidden rules are further classified as *general redundant* if all the rules hiding them enforce the same action (as presented in Figure 45.9a), and *general shadowed*, if at least one enforces a different action (as presented in Figure 45.9b).

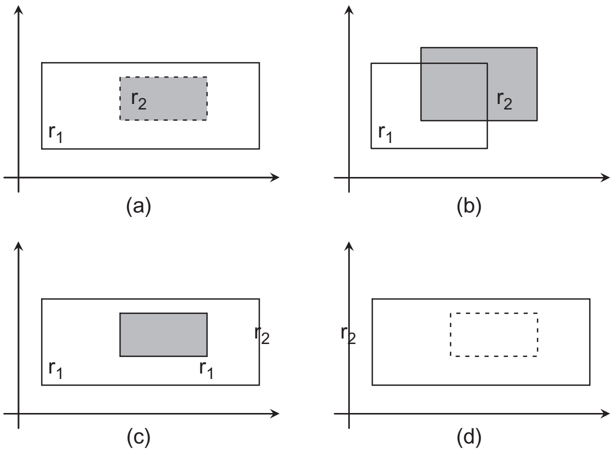

FIGURE 45.8 Al-Shaer's rule-pair anomaly classification for packet filters.

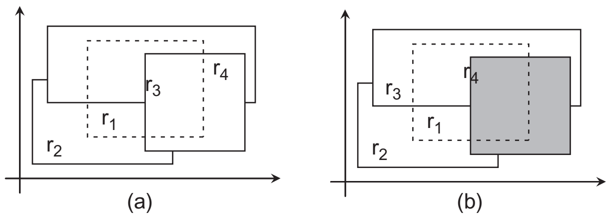

FIGURE 45.9 Multi-rule anomaly classification.

A More in-Depth View of Packet Filter Conflict Analysis

Al-Shaer's classification is the starting point for several works that tried to improve the identification of the anomalies using different techniques. Bouhoula [31] used rule field logical relations, so permitting the analysis of different firewall rule formats, not only the five-tuples. Thanasegaran [32] used bit vectors that support the detection of rule-pair anomalies more efficiently and the definition of new fields, but they fail to effectively express conditions on ordered fields (ranges of port numbers). Ferraresi [33] presented a slightly alternative conflict classification and a proven correct algorithm that produces a conflict-free rule list. Other works propose ruleset optimization by redundancy removal, Gouda [34] provided algorithms to verify the consistency, completeness, and compactness of packet filters, and Liu [35] introduced techniques for detection of redundancy based on Firewall Decision Diagrams. Alfaro [36] proposed a set of algorithms to remove anomalies between packet filters and NIDS in distributed systems, recently implemented in the MIRAGE tool [37]. Hu [38] also introduced an ontology-based anomaly management framework that delegates set operations to binary decision diagrams (BDDs). A completely different approach is presented by Bandara [39], who uses argumentation logic and achieves excellent performance. A

TABLE 45.1 A Sample Filtering Policy with Anomalies.

	priority	source IP	source port	dest IP	dest port	protocol	action
r_1	1	10.0.0.64/28	any	1.1.1.64/28	80	TCP	DENY
r_2	2	10.0.0.0/24	any	1.1.1.0/24	80	TCP	ALLOW
r_3	3	10.0.0.2	any	1.1.1.1	80	TCP	DENY
r_4	4	10.0.0.250	any	1.1.1.1	80	TCP	ALLOW
r_5	5	10.0.0.16/24	any	1.1.1.16/24	80	TCP	DENY
r_6	6	5.5.5.5	any	6.6.6.6	any	any	ALLOW

complementary approach is represented by Liu's Firewall Compressor [40], which minimizes the ACL size by manipulating the specified rules to obtain an equivalent ACL with a minimal number of rules. Redundant and shadowed rules disappear, but correlated rules are not examined. The compressed ACL only serves deployment purposes, as it is no longer manageable by the administrators.

Stateful Firewall Analysis

Anomaly analysis of stateful firewalls is a less explored field. It is difficult to share the optimism of Buttyàn [41], who stated that "stateful is not harder than stateless." Their scenario is oversimplified, as they added one single field to the five-tuple decision space to describe all the possible states. The stateful case is harder at least for two reasons: There are new anomalies that do not appear in the stateless case, and it is computationally more complex as many fields need to be considered. Gouda and Liu presented in [42] a model of stateful firewalls that maps the stateful filtering functionalities to the packet filter case, in order to use the available detection algorithms. For this reason, they model stateful firewalls using two components: the stateful section and the stateless section. The stateful section inspects the transport headers and maintains a *state table* that associates each of the connections observed with a set of Boolean variables, for example, the established state for the TCP connections. A set of (hard-coded) *stateful rules* regulates how the state table is updated, according to previous states and received packets. The stateless section is simply a packet filter that also includes predicates over the boolean variables in the state table, and the anomalies found are Al-Shaer's. Cuppens [43] extended Al-Shaer's classification adding stateful conflicts, situations connected to the specific protocol state machines, for example, rules that deny TCP setup and termination for allowed connections, or rules that block allowed related FTP connections.

Finally, there is currently no extensive work to detect anomalies in application firewalls, if we exclude the effort to validate the factory-provided regular expressions used to avoid attacks in Web application firewalls. An example representative of the complexity of the analysis in this case is described by the following rules (the first rule is used to avoid DoS attacks):

1. Deny packets with the SYN and ACK set to true from the external nodes;
2. Allow TCP connections from the internal node having IP 1.1.1.1 to the external server 2.2.2.2 (in the Internet).

These rules are apparently disjoint, as one poses a condition on different values of the IP addresses and TCP flags. However, according to the TCP specification, the three-way handshake cannot be terminated; the result then is that the connection from 1.1.1.1 and 2.2.2.2 is forbidden (see Figure 45.10).

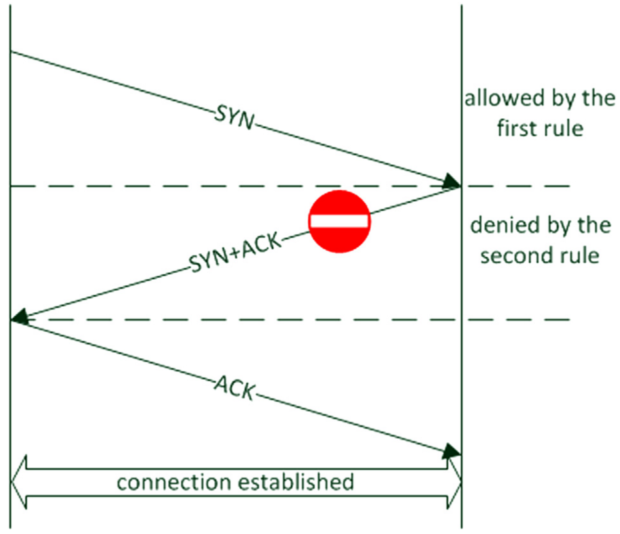

FIGURE 45.10 Blocked three-way handshake.

Inter-Firewall Analysis

Al-Shaer [44] has also provided the first classification of anomalies in distributed systems. He considers the case of two serially connected stateless firewalls, named, respectively, upstream and downstream firewalls. Assuming fw_u is the upstream firewall and fw_d is the downstream firewall, four anomaly types are identified:

- *Shadowing anomaly*—occurs if fw_u blocks traffic accepted by fw_d (see Figure 45.11a);
- *Spuriousness anomaly*—occurs if fw_u permits traffic denied by fw_d (see Figure 45.11b);
- *Redundancy anomaly*—occurs if fw_u denies traffic already blocked by fw_u (see Figure 45.11c);
- *Correlation anomaly* occurs when a rule *ru* in fw_u and a rule *rd* in fw_d are correlated (see Figure 45.11d).

Another work that addresses conflict analysis in distributed systems is presented in [42]. This work defines for every pair of nodes in the network two separate end-to-end policies: the allowed packets, named accept property, and the denied packets, named discard property. Based on an abstract representation of the firewall ACL, the Firewall Decision Diagram [32], they calculate the effects on the communication between two nodes n_1 and n_2 by superposing the actions taken by all the cascading firewalls encountered in the path between n_1 and n_2. Then, they compare the results with the accept and discard properties; a conflict arises when an accept or

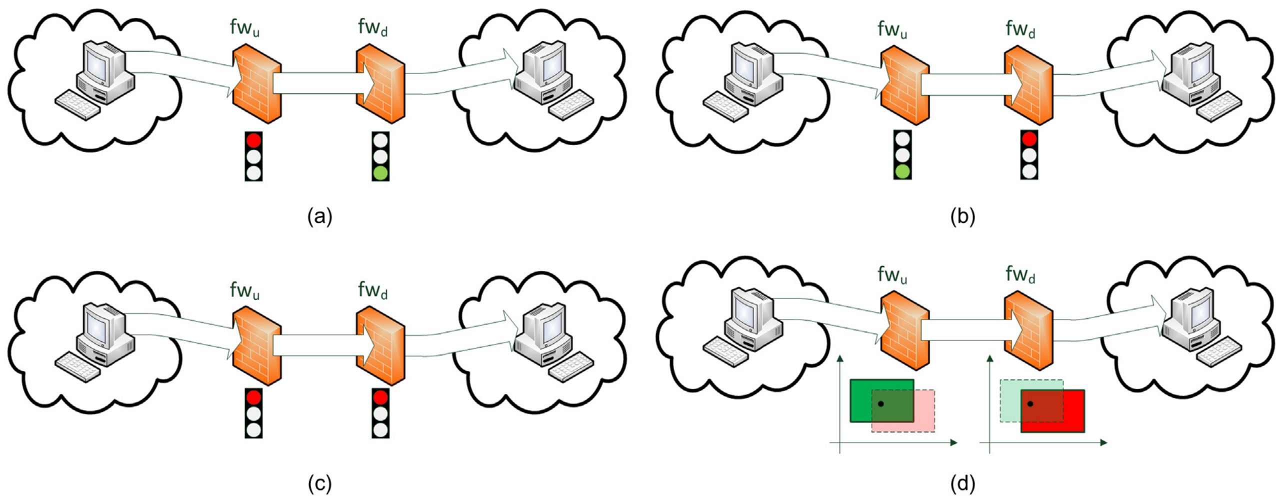

FIGURE 45.11 Al-Shaer's rule-pair anomaly classification for distributed packet filters.

discard property is not satisfied. Finally, a tool able to detect Al-Shaer's anomalies in distributed systems is FIREMAN, which also checks if a distributed policy complies with an end-to-end policy [43].

Channel Protection Conflicts

The configuration of secure channels is also an error-prone activity; thus administrators need assistance and conflict detection mechanisms. A few differences can be highlighted with respect to the filtering case: The number of rules is usually orders of magnitude less than in the firewall case. However, they enforce more complex actions, they may enforce more than one action in case of multiple matches, and they have more complex dependencies on the actual distributed system topology.

Different technologies are available to protect channels, and these technologies work at different levels of the ISO/OSI stack. The most well-known solutions are: IPsec, which works at the network layer; and the TLS protocol, which works up to the transport layer. IPsec allows the creation of secure communication channels between two endpoints. IPsec can enforce authentication and integrity of IP payload and header using the Authentication Header (AH) protocol, and confidentiality, authenticity, and integrity of the IP payload using the Encapsulating Security Payload (ESP). These endpoints can be the communicating peers (client and server or two peers) or two gateways used to allow securely connecting two subnets or two offices connected over a public/insecure network (the Internet) and to establish a virtual private network (VPN). Also, TLS is used as the base protocol to create VPNs; when this technology is employed, the terms *OpenVPN* or *clientless VPN* are used. These techniques have many similarities from the configuration point of view; therefore they share the same anomalous situations. However, only IPsec VPNs have received attention from researchers, nevertheless, the results on IPsec VPNs are easily extendable to the OpenVPN scenario.

IPsec Intra-Policy Conflict Detection

The IPsec configuration rules (the Security Policy) are stored in the local Security Policy Database (SPDB). These rules select the traffic to be protected by means of (condition clause) predicates on the source and destination IP addresses, IP protocol type fields, and traffic direction (in/out). Three types of anomalies can be found in this scenario: (intra-policy) local anomalies, (intra-policy) topology-dependent local anomalies, and inter-policy anomalies.

Local anomalies are analogous to the packet filter scenario (see checklist:"An Agenda for Action for Developing Security Policies for Packet Filtering), and they can be identified using the same techniques (only a simple adaptation is needed). It is not surprising that Al-Shaer proposed the application of its classification for packet filters presented in [10] to intra-IPsec policy analysis [45], extending an early work from Fu et al. [46].

The anomaly types are exactly the same: shadowed, redundant, correlated, and generalized rule pairs can be found in an IPsec SPDB. However, the effort required for the analysis is greater. The main difference is that the actions that can be enforced using IPsec are more complex, as confidentiality, authenticity, and integrity (of the IP payload only using ESP, or IP payload and header using AH) can be selected. Moreover, cryptographic algorithms need to be evaluated and compared. For instance, is it better to protect a channel using "ESP with HAMC-SHA1

An Agenda for Action for Developing Security Policies for Packet Filtering

IPSec can perform host-based packet filtering to provide limited firewall capabilities for end systems. You can configure IPSec to permit or block specific types of unicast IP traffic based on source and destination address combinations and specific protocols and specific ports. For example, nearly all the systems illustrated in the following checklist can benefit from packet filtering to restrict communication to only specific addresses and ports. You can strengthen security by using IPSec packet filtering to control exactly the type of communication that is allowed between systems (check all tasks completed):

_____**1.** The internal network domain administrator can assign an Active Directory-based IPSec policy (a collection of security settings that determines IPSec behavior) to block all traffic from the perimeter network (also known as a demilitarized zone [DMZ], demilitarized zone, or screened subnet).

_____**2.** The perimeter network domain administrator can assign an Active Directory-based IPSec policy to block all traffic to the internal network.

_____**3.** The administrator of the computer running Microsoft SQL Server on the internal network can create an exception in the Active Directory-based IPSec policy to permit Structured Query Language (SQL) protocol traffic to the Web application server on the perimeter network.

_____**4.** The administrator of the Web application server on the perimeter network can create an exception in the Active Directory-based policy to permit SQL traffic to the computer running SQL server on the internal network.

_____**5.** The administrator of the Web application server on the perimeter network can also block all traffic from the Internet, except requests to TCP port 80 for the HyperText Transfer Protocol (HTTP) and TCP port 443 for HTTPS (HTTP over Secure Sockets Layer/Transport Layer Protocol [SSL/TLS]), which are used by Web services. This provides additional security for traffic allowed from the Internet in case the firewall was misconfigured or compromised by an attacker.

_____**6.** The domain administrator can block all traffic to the management computer, but allow traffic to the perimeter network.

and AES256" or a channel using "ESP with RC2128 encapsulated in AH with HMAC-MD5"? The answer is not easy and depends on the requirements specified at the business level.

Together with the previous anomalies, other types of anomaly appear from the analysis of a local SPDB: the intra-policy channel overlapping and the multitransform anomalies. These anomalies depend on the possibility of applying in the same SPDB more than one transformation; choosing the correct order, modes, and algorithms becomes crucial.

The overlapping occurs when a SPDB contains more than one rule having the same source s and destination d that use different tunneling devices, g_1 and g_2 (see Figure 45.12). For instance, if the SPDB contains the following rules:

- (short tunnel) tunnel to g_1 with protection p_1
- (long tunnel) tunnel to g_2 with protection p_2

and are applied in this order, the following communications are performed:

1. $s \rightarrow g_2$ protected with p_1 and p_2
2. $g_2 \rightarrow g_1$ protected with p_1 (p_2 is removed at g_2)
3. $g_1 \rightarrow d$ with no protection

Therefore, the rule order matters. In fact, if the rules are applied in the opposite order, the communications are, as expected:

1. $s \rightarrow g_1$ protected with p_1 and p_2
2. $g_1 \rightarrow g_2$ protected with p_2 (p_1 is removed at g_1)
3. $g_2 \rightarrow d$ with no protection

This anomaly can also occur with a transport transform (instead of the long tunnel) followed by a tunnel (short tunnel). Applying more than one transformation increases the risk of reducing the protection level. In fact, it is not always true that the combination of more transformations results in a stronger protection. Moreover, since the application of each transformation requires computational resources, using more than one transformation must be justified from the security point of view. The multitransform anomaly occurs when a weaker protection is applied after a stronger one. For instance, applying ESP after AH reduces the overall security because ESP transport does not provide IP header protection. On the other hand,

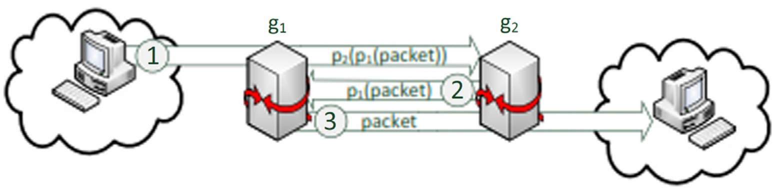

FIGURE 45.12 IPsec intra-policy overlapping conflict.

applying AH after ESP is often justified to preserve the header integrity. Additionally, a multitransform anomaly may also occur when the increase of cost/benefit in terms of security is not justified, as when one is applying ESP with AES256 after having applied ESP with AES128. Resolving these anomalies is very delicate. Every case needs to be considered individually, as the "protection strength" needs to be measured and compared to the performance loss, but an official measure does not exist and every organization may have its own evaluation criteria.

IPsec Inter-Policy Conflict Detection

Together with the explicit deny action, communications can also be blocked in case of misconfigurations or if the peer authentication fails, if the *security association* defining the algorithms and keys to use to protect the channel is not available and not negotiable, or if there is more than one security association when a unique security association is expected. Therefore, the types of anomaly are analogous to the ones presented in distributed systems. In fact, IPsec communications can be shadowed (block traffic already blocked by the upstream device) and spurious (allow traffic already blocked by the upstream device).

Additionally, it is possible to highlight the *inter-policy channel overlapping*, presenting the same mechanism as the intra-policy case but involving more than two elements. To protect communication between source s and destination d, there are three gateways, g_1, g_2, and g_3, which are encountered in this order by packets from s to d (see Figure 45.13). The following policy is enforced:

- s creates a secure channel (transport mode) to g_2 with protection p_1.
- g_1 creates a tunnel to g_3 with protection p_2.

Therefore, the resulting communications are:

1. $s \rightarrow g_1$ protected with p_1
2. $g_1 \rightarrow g_3$ protected with p_1 and p_2
3. $g_3 \rightarrow g_2$ protected with p_1 (p_2 is removed at g_3)
4. $g_2 \rightarrow d$ with no protection

IPsec devices are managed by different people often working in different units; therefore the inter-policy conflicts are relatively frequent. Sun et al. [47] proposed a new architecture that stores all the IPsec policy centrally and offers access via a manager which also enforces an access control policy. Additionally, the proposed work aims at automatically manipulating the SPDB to avoid or recover some of the anomalies presented before.

6. SEMANTIC WEB TECHNOLOGY FOR CONFLICT DETECTION

The term *Semantic Web* refers to both a vision and a set of technologies. The vision is articulated, in particular by the World Wide Web Consortium (W3C), as an extension to the current idea of the Web in which knowledge and data could be published in a form easy for computers to understand and reason with. Doing so would support more sophisticated software systems that share knowledge, information and data on the Web just as people do by publishing text and multimedia. Under the stewardship of the W3C, a set of languages, protocols, and technologies have been developed to partially realize this vision, to enable exploration and experimentation, and to support the evolution of the concepts and technology. The current set of W3C standards is based on RDF [48], a language that provides a basic capability of specifying graphs with a simple interpretation as a *semantic network* and serializing them in XML and several other popular Web systems (e.g., JSON). Since it is a graph-based representation, RDF data are often reduced to a set of triples where each represents an edge in the graph or, alternatively, a binary predicate. The Web Ontology Language (OWL) [49] is a family of knowledge representation languages based on Description Logic (DL) [50] with a representation in RDF. OWL supports the specification and use of ontologies that consist of terms representing individuals, classes of individuals, properties, and axioms that assert constraints over them.

The use of OWL to describe and verify the properties of policies offers several important advantages, which are particularly critical in distributed environments possibly involving coordination across multiple organizations. First, most policy languages define constraints over classes of targets, objects, actions, and other kinds of information (location). A substantial part of the development of a policy is often devoted to the precise specification of these classes. This is especially important if the policy is shared between multiple organizations that must adhere to or enforce the policy, even though they have their own native schemas or data models for the domain in question. The

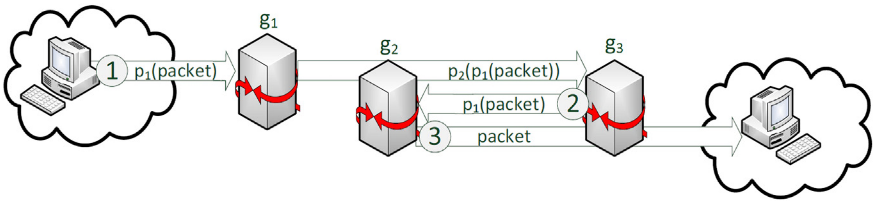

FIGURE 45.13 To protect communication between sources and destination d, there are three gateways: g_1, g_2, and g_3.

second advantage is that OWL's grounding in logic facilitates the translation of policies expressed in OWL to other formalisms, either for further analysis or for execution.

Semantic Web technology offers an extensive collection of tools that can be used to model and represent policy conflicts. Several approaches can be adopted, with different profiles in terms of abstractness and efficiency. There are three main approaches to discover conflicts: standard reasoners, ad-hoc reasoning methods, and rule-based inferencing. In the next subsections we characterize these three alternatives.

Use of Standard Reasoners

The standard reasoner is one of the core elements of an ontology-based system. Starting from the information contained in the ontology described in OWL, it is able to perform several tasks (it is able to check the consistency and validity of the ontology, classify its information, answer queries, and generate inferences) using a variety of techniques deriving from the work of the artificial intelligence community.

In particular, standard *Description Logic* (DL) reasoning performed w.r.t. a formal ontology can check complex consistency constraints in the model. Such constraints are different from the usual ones from database and *UML*-like systems. In OWL-DL, which is the portion of OWL restricted to the expressivity of DL, we can express:

- Constraints on properties, domains, and ranges
- Definitions of concepts (classes) in terms of relationships with other elements
- Boolean operations on classes

One of the main differences between DL-based schema definitions and UML or ER definitions concerns the constraints on property domains and ranges. Properties can be defined in a general way, and their behavior in terms of range type can be precisely described while refining the ontology concepts. This promotes the definition and reuse of high-level properties, without losing the ability to force precise typing. In this way, the resolution of some conflicts can be explicitly expressed in the policy, without the need to rely on an external conflict resolution option or implicit priorities. For instance, authorizations associated with a subject administrator can be denoted as having higher priority, dominating in possible conflicts with other authorizations.

Ad-Hoc Reasoning Methods

Standard *Description Logic* reasoners can answer complex questions and verify structural and nonstructural constraints. Furthermore, DL-based language expressiveness often exceeds classical solutions (like UML for design and SQL for data storage models). This supports the description and verification of more complex structural constraints. For example, if we consider the approach used in [51], where the roles are represented as individuals of the class Role, the $roleHierarchy : Role \rightarrow Role$ property[3] is used to connect each role to its direct subroles and the $canHaveRole+: Identity \rightarrow Role$ property is used to represent the roles that each identity (user) can activate, directly or indirectly, thanks to the presence of positive role authorizations. Thus, *roleHierarchy* (r_1, r_2) means that role r_1 is a super-role of r_2. Its transitive closure $canBe+: Role \rightarrow Role$ can be used to identify all the direct or indirect subroles. The subrole (as well as its inverse super-role) relationship is not a containment and does not define a taxonomy on identities (a super-role of role R is intended to be more privileged than R and is available to a more restricted set of identities).

With these tools it is possible, for instance, to offer an immediate management of Separation of Duty constraints. The user role assignment relation is represented using role authorizations, which specialize authorizations with the specification of the role that the principal is allowed or forbidden to assume. A Separation of Duty constraint between role r_1 and r_2 can then be expressed using a negative role authorization r_{auth} that forbids role r_1 to enact role r_2. Separation of Duty constraints are enforced both at the role hierarchy level (in this way we directly prevent a role r_1 from being declared super-role of another role r_2, such that r_1 and r_2 are in a SoD constraint) and at the user hierarchy level (to prevent two roles r_1 and r_2 from being assigned to a user, directly or indirectly, that are involved in a SoD constraint).

To show a more concrete example, we assume that class $RoleAuthorization \subseteq$ Authorization represents the role authorizations, and properties *grantedTo*: $RoleAuthorization \rightarrow Principal$ and *enabledRole*: $Role\ Authorization \rightarrow Role$ are used to represent, respectively, the role enabled by the role authorization and the principal to which the role is assigned. In order to keep track of all SoD conflicts on roles, we can define a class $SoDOnRole \subseteq Role$. Separation of Duty constraints on the role hierarchy can be expressed adding to the ontology the following set of axioms:

$$\forall auth \in RoleAuthorization{:}sign(auth, -),\\ grantedTo(auth, r_1), enabledRole(auth, r_2)$$

$$SoDOnRole \equiv \exists canBe+.\{r_1\} \cap \exists canBe+.\{r_2\}$$

The interpretation of these axioms is that, for each negative role authorization, there is an instance in class

3. The notation "$R : A \rightarrow B$" has to be interpreted according to Description Logic conventions. It states that A and B are, respectively, the domain and the range of the property R, with no further constraints about the functionality or completeness of R.

SoDOnRole only if there exists a single role that belongs to r1 and to r2. We can thus enforce the SoD at the role hierarchy level by simply adding the axiom $SoDOnRole \sqsubseteq \perp$ to the ontology, which declares as consistent the ontology only if the class is empty.

In a similar way to what we have done for the identification of SoD conflicts at the role hierarchy level, we can define a class $SoDOnUser \sqsubseteq Identity$ that keeps track of the conflicts on the user hierarchy. We then express SoD constraints using the following axioms:

$$\forall auth \in RoleAuthorization{:}sign(auth, -), \\ grantedTo(auth, r_1),\ \ enabledRole(auth, r_2)$$

$$SoDOnUser \equiv \exists canHaveRole + .\{r_1\} \cap \exists canHaveRole \\ + .\{r_2\}$$

and to enforce the SoD constraints we simply have to add to the ontology the axiom $SoDOnUser \sqsubseteq \perp$.

This approach can be easily extended to handle other kinds of SoD constraints, such as *Permission-based SoD* (which requires that no user be allowed to do both actions a_1 and a_2) or *Object-based SoD* (which requires that no user can access both resources res_1 and res_2). However, DL systems, as well as *Semantic Web* tools in general, are designed and implemented with a focus on knowledge management services, such as knowledge integration, schema matching, and instance retrieval. Such a specialization raises some limitations on the use of pure DL reasoning in real scenarios, in which reasoning must be carried out on a well-defined and complete description of a closed system.

Closed World Assumption (CWA)

Closed World Assumption (CWA) reasoning is a generally accepted requirement in model-driven systems. Conversely, DL reasoners usually work under the Open World Assumption (OWA). This means that the facts asserted in the model (about the layout topology or the authorization policies) are not assumed to be complete. Obviously, this can become a problem if model characteristics are described in terms of the existence of some properties or some relationships between model elements.

Reasoning on Complex Property Paths

Reasoning on complex property paths (commutatively of nontrivial graphs) rapidly brings to the undecidability of the formal logics the language is based on. Checking the closure of complex paths is beyond the expressive power of classical database systems, but unfortunately it is sometimes necessary in order to check structural constraints. This is the case, for example, for the consistency loop in Figure 45.14, stating that:

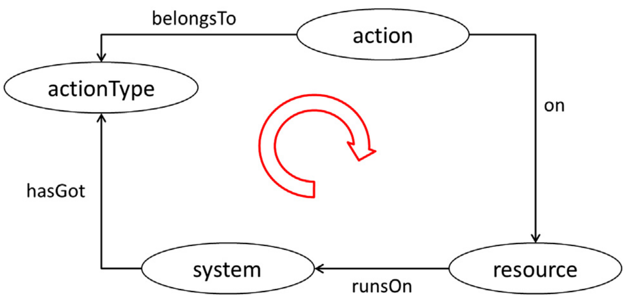

FIGURE 45.14 A simple consistency constraint.

an authorization of executing an action must be assigned to a resource (Database) that runs on a system (DBMS) compatible with the action type (Select, Create, Delete).

Unique Name Assumption (UNA)

Unique Name Assumption (UNA) is a commonly accepted assumption in most model-driven tools. It consists in assuming that different names will always denote different elements in the model. This is usually not true in DL reasoners because of the essential nature of knowledge integration problems. In fact, in the Semantic Web scenario, different authors may describe the same entities (both shared conceptualizations and physical objects), assigning a new name, generally in the form of an URI, defined independently from other users.

These properties must be carefully considered when applying DL and Semantic Web tools to the detection of policy conflicts. The obstacles introduced can be solved as long as attention is paid to them. Misbehaviors of the system can otherwise be observed.

Rule-Based Inferencing

Rule inference reasoning is widely used in knowledge management systems. Recently, some combinations of theorem proving systems (like DL ones) and rule inference systems have been proposed, to address some limitations of decidable theorem proving systems.

Semantic Web Rule Language (SWRL) is the W3C standard proposal for integrating rule-based inferencing into systems that represent knowledge as a set of RDF triples and introducing some limitations to the use of the rules, in order to preserve joint system decidability. In a real scenario, the main advantage of combining rules and classical theorem-proving systems is the support for complex property chains. In fact, even if some *OWL* profiles introduce the support for the chaining of properties (a.k.a roles in DL terminology), this may not be sufficient to express some complex topological properties. For example, the simple consistency loop shown in Figure 45.14 is not enforceable at the schema level using only DL axioms. In order to

perform a consistency check on Figure 45.14, a simple SWRL rule like this one is needed:

$on(?a_1, ?r_1), belongsTo(?a_1, ?act_1), runsOn(?r_1, ?s_1), hasGot(?s_1, ?act_2), differentFrom(?act_1, ?act_2) -> Error(?a_1, Error)$

The above SWRL rule verifies whether there is an action a1 belonging to action type act1 that is applied to resource r1, which runs on service s1, which has an action type act2; if act1 and act2 are verified to be incompatible (using the *differentFrom* predicate), an instance of class Error is created, recording a1. Essentially, using this rule we can verify that all the *system* instances on which the action is granted are compatible with the *actionType*. Violations are recorded into Error.

As a technical note, we observe that as a general outcome of the adoption of the *Open World Assumption*, even if we could enforce the existence of the loops, we would not be able to require that such loops be explicitly stated into the assertional part of the semantic model (*A-box*). At the opposite end, due to decidability issues (DL safe rules), the rule-based component of the language operates in a kind of *Closed World Assumption* (CWA) limited to the nodes. This means that a forward chaining rule can be triggered by any property derived by the reasoning, but involving only nodes that are explicitly named in the A-box. Then, we can operate only on nodes and properties explicitly stated in the semantic model. Furthermore, rules can freely combine as antecedent triple patterns to capture complex topological structures, and this solves the lack of complex property chains of *Description Logics*. This means that we can check for loops, or for the absence of loops, by adding custom rules to the ontology. However, SWRL safe rules can consume only positive knowledge, so they can be used to directly detect errors that consist in the existence of some structure in the ontology, that is, the existence of a loop.

To summarize, Semantic Web technology offers an interesting potential for detecting conflicts in a variety of settings. The integration with a rich environment of tools, open source and commercial, together with the increasing familiarity that users are acquiring on them, makes this option particularly interesting for the realization of sophisticated conflict-detection solutions. These approaches support the flexible definition and identification of conflicts, going beyond the classifications introduced in this chapter and adapting the model to the specific requirements of every application scenario.

7. SUMMARY

The detection and management of conflicts in security policies is an important topic for both the research and industrial community. The chapter was not exhaustive in its treatment of the topic, though it is quite extensive. The goal was to focus on the detection of conflicts, considering abstract and executable policies, and illustrating in greater detail the detection of policy conflicts in computer networks, which is the area that today sees the greater industrial support. Support in industrial products can be expected to appear in the near future for security policies in other scenarios and at a variety of abstraction levels. The discussion of Semantic Web technology has shown how this family of tools can be applied to this task, offering a strategy that can be of particular interest for deployment in real systems.

We expect that conflict detection techniques will become common components of tools for the design and configuration of security. The *PoSecCo* project, which is described in Chapter 23, aims at realizing a policy-based security management, and it represents an interesting example of such a system.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The evolution of information systems is continuously increasing the capabilities and range of offered services, leading to infrastructures that see the participation of a larger number of users, a greater level of integration among separate systems, and a correspondingly larger impact of possible misbehaviors.
2. True or False? A typical top-down representation of the protection of an information system might consist of five layers.
3. True or False? Security requirements are a low-level, declarative representation of the rules according to which access control must be regulated.
4. True or False? Policies represent how security requirements are mapped to the systems used for service provisioning.
5. True or False? Abstract policies provide a formal representation of access control and its behavior.

Multiple Choice

1. What describes the access control policy in a way that can be immediately processed by an access control component?
   - **A.** Privacy-enhancing technology
   - **B.** Location technology
   - **C.** Web-based

D. Executable policies
E. Data controller

2. What mechanisms correspond to the low-level functions that implement the executable policies?
A. Policy enforcement
B. Location technology
C. Valid
D. Privacy-enhancing technologies
E. Web technology

3. What conflicts arise when principals are authorized to do an action *a* on a resource *r* by *a* positive authorization, and forbidden to do the same action *a* on the resource *r* by a negative authorization?
A. Data minimization
B. *XACML*
C. Private information
D. Contradictory
E. Security

4. What conflicts arise when an authorization is dominated by other authorizations and does not contribute to the policy (its removal would not modify the behavior of the system)?
A. Privacy metrics
B. Retention time
C. Redundant
D. Privacy preferences
E. Taps

5. What conflicts occur when the conflict can never manifest itself in a system?
A. Irrelevant
B. Anonymous communication
C. Data-handling policies
D. Disclose-to
E. Social engineering

EXERCISE

Problem

What is meant by the phrase "where technically feasible?"

Hands-On Projects

Project

What is meant by the phrase "reasonable business judgment?"

Case Projects

Problem

What is meant by *data, documents, documentation*, "*logs*, and *records*? What are the differences between these terms?

Optional Team Case Project

Problem

What are some sample security policy test procedures?

ACKNOWLEDGMENTS

This work was partially funded by the European Community in the scope of the research project PoSecCo (project no. 257129), under the Information and Communication Technologies (ICT) theme of the 7th Framework Programme for R&D (FP7). The work by Stefano Paraboschi was partially supported by the PRIN 2008 project PEPPER (2008SY2PH4) and the PRIN 2010-11 project GenData-2020.

1. INTRODUCTION

The advancements in Information and Communications Technology (ICT) allow users to take more and more advantage of the availability of online services (and resources) that can be accessed anywhere anytime. In such a scenario, the server providing the service and the requesting user may be unknown to each other. As a consequence, traditional access control systems [1] based on the preliminary identification and authentication of users requesting access to a service cannot be adopted and are usually not suited to open scenarios [2−4]. The solutions proposed to allow servers to regulate access to the services they offer, while not requiring users to manage a huge number of accounts, rely on *attribute-based access control* mechanisms [5−13]. Policies regulating access to services define conditions that the requesting client must satisfy to gain access to the service of interest. Upon receiving a request to access a service, the server will not return a yes/no reply, but it will send the client the conditions that she must satisfy to be authorized to access the service. To prove to the server the possession of the attributes required to gain the access, the client releases *digital certificates* (*credentials*) signed by a trusted third party, the *certification authority*, who declares under its responsibility that the certificate holder possesses the attributes stated in the certificate. Practically, credentials are the digital representation of paper certificates (id card, passport, credit card). The adoption of credentials in access control has several advantages. First, credential-based access control enables clients to conveniently access Web services, without the need to remember a different <*username*, *password*> pair for each system with which she wants to interact. Second, it offers better protection against adversaries interested in improperly acquiring users' access privileges.

The use of credentials to enforce access control restrictions in open environments has been widely studied in the last 15 years. Most attention has, however, been devoted to the server side of the problem, proposing a number of novel *policy languages*, for specifying access control rules [5,6,11−13]; *policy engines*, for the evaluation of access requests and the enforcement of policy restrictions [10,11,13,14]; and strategies for *communicating* access conditions to the requesting clients, possibly engaging a negotiation protocol [10,11,13−18]. Since the interacting parties are assumed to be unknown to each other, the client may not know which attributes/credentials to release to gain access to the service of interest. As a consequence, the server should send the client its policy, which may, however, be considered sensitive and therefore needs to be adequately protected before being disclosed. Most of the current approaches implicitly assume that clients adopt an approach symmetrical to the one used by servers for regulating access to the sensitive information certified by their credentials. Although these solutions are expressive and powerful, they do not fully support the specific protection requirements of the clients. In fact, clients are interested in a solution that is expressive and flexible enough to support an intuitive and user-friendly definition of the sensitivity/privacy levels that they perceive as characterizing their data. These preferences are used to choose which credentials to release when more than one subset of credentials satisfy the access control policy defined by the server (to buy a medicine, a patient needs to prove her identity by releasing either her identity card or her passport).

This chapter provides an overview of the privacy issues arising in open environments, both from the client and from the server points of view, and illustrates some solutions proposed to overcome these problems. The

remainder of this chapter is organized as follows. Section 2 introduces basic concepts and describes the desiderata of privacy-aware access control systems operating in open environments. Sections 3, 4, 5, and 6 illustrate some recent proposals that permit clients to specify privacy preferences that are then used to determine which credentials to disclose to gain access to a service of interest. Section 7 focuses on the server side of the problem, describing approaches that permit regulating the disclosure of sensitive access control policies. Section 8 presents some open issues that still need to be addressed. Finally, Section 9 presents our summary and concluding remarks.

2. BASIC CONCEPTS AND DESIDERATA

In this section, we describe the concepts that are the basis of the proposals we will describein the chapter, and we discuss the desiderata that an attribute-based access control system should satisfy to effectively support both client and server privacy preferences.

Client Portfolio

The information that a client can provide to a server to gain access to a service is organized in a *portfolio* including both *credentials* signed by third parties and certifying client properties, and *declarations* stating uncertified properties uttered by the client [6]. Each credential c in the client portfolio is characterized by: a unique identifier $id(c)$, an issuer $issuer(c)$, a set of attributes $attributes(c)$, and a credential type $type(c)$. The type of credential determines the set of attributes it certifies. Credential types are traditionally organized in a rooted *hierarchy*, where intermediate nodes represent abstractions defined over specific credential types that correspond to the leaves of the hierarchy [19]. Formally, a hierarchy H of credential types is a pair $(T, \leq_{isa})$, where T is the set of all credential types and abstractions defined over them, and $\leq_{isa}$ is a partial-order relationship on T. Given two credential types t_i and t_j, $t_i \leq_{isa} t_j$ if t_j is an abstraction of t_i. For instance, *photo_id* is an abstraction of credential types *id_card* and *passport* (i.e., $id\_card \leq_{isa} photo\_id$ and $passport \leq_{isa} photo\_id$). The root of the hierarchy is node *, representing any credential type. We note that declarations are usually modeled as a type of credential, signed by the client herself. Figure 46.1 illustrates a hierarchy of credential types.

The hierarchy of credential types is a knowledge shared between the client and the server. In fact, while a client knows exactly the different instances of credential types composing her portfolio, the server formulates its requests over credential types since it cannot be aware of the instances composing the client portfolio. We note that a client may possess different credentials of the same type (she can have more than one credit card).

Depending on the cryptographic protocol used for their generation, credentials can be classified as *atomic* or *nonatomic*. Atomic credentials are the most common kind of credentials used today in distributed systems (X.509 certificates) and can only be released as a whole. As a consequence, even if an atomic credential certifies attributes that are not required to gain access to a service, if the client decides to release it, these attributes will be disclosed to the server. Nonatomic credentials have recently been proposed as a successful approach to limit data disclosure (U-Prove and Idemix [20,21]). Credentials generated adopting these technologies permit the client to selectively release a subset of the attributes certified by the credential (as well as the existence of the credential itself). Note that the release of an attribute (or a set thereof) certified by a nonatomic credential entails the disclosure of the existence in the client portfolio of the credential itself. Clearly, declarations are nonatomic credentials.

Attributes within credentials are characterized by a *type*, a *name*, and a *value* (attribute *Name* of type *Name* with value *Bob*), which can either depend only on the client or on the specific credential certifying the attribute. In the first case, the attribute is *credential-independent* since

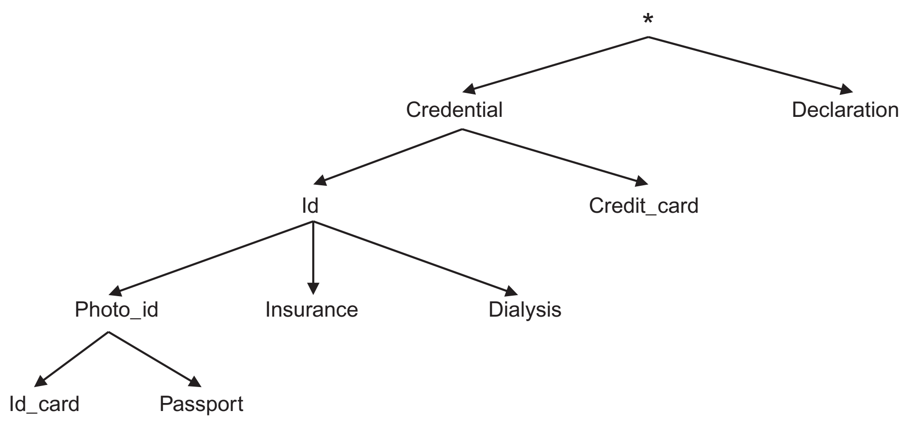

FIGURE 46.1 An example of hierarchy of credential types.

TABLE 46.1 An Example of a Client Portfolio.

id(c)	Atomic	Type(c)	Attributes(c)
MyIdCard	✓	id_card	Name, DoB, City
MyPassport		passport	Name, DoB, Country
MyVISA	✓	credit_card	Name, *VISANum*, *VISALimit*
MyAmEx	✓	credit_card	Name, *AmExNum*, *AmExLimit*
MyDialysis		dialysis	Name, City
MyInsurance	✓	insurance	Name, *Company*, *Coverage*
MyDecl		declaration	Name, DoB, City, Country, *VISANum*, *VISALimit*, *AmExNum*, *AmExLimit*, *Company*, *Coverage*, e-mail

its value is the same, independently from the credential certifying it (*Name* and *DoB* are credential-independent attributes). In the second case, the attribute is *credential-dependent* since its value depends not only on the credential holder, but also on the specific instance of the credential certifying it (attribute type *CCNum*, representing the credit-card number, is a credential-dependent attribute since each credit card has a different number).

For instance, Table 46.1 illustrates a client portfolio composed of four atomic and three nonatomic credentials. In the table, credential-independent attributes are in roman, while credential-dependent attributes are in *italic*.

Disclosure Policies

Attribute-based access control restricts access to server service, depending on the attributes and credentials that the requesting client discloses to the server. The policy regulating access to services is therefore defined over attributes and credentials provided by clients. Since the server may not know the requesting client and therefore will ignore the credential instances in her portfolio, the access control policy is defined considering only the hierarchy of credential types, which represents a common knowledge to the interacting parties. An access control policy is defined as a Boolean formula composed of basic conditions *cond* of the form ($term_1$ o $term_2$), where o is a predicate operator ($>$, $<$, $=$), and $term_1$ and $term_2$ are its operands. The operands of a basic condition can be either constant values or (certified or declared) attributes represented by terms of the form $c.a$, where c is a variable representing a credential and a is the name of the attribute. For instance, basic condition $Coverage > 10{,}000$ USD requires that the coverage offered by insurance is higher than 10,000 USD to access the service. The server may also define restrictions on the type of credentials that should certify the requested attributes and/or require that a set of attributes in the policy are certified by the same credential. As an example, policy $(type(c) = insurance) \wedge (c.Company \neq \text{'A'}) \wedge (c.Coverage > 10{,}000 \text{ USD})$ requires that attributes *Company* and *Coverage* are certified by the same credential c, of type *insurance*.

Trust Negotiation

Since clients and servers operating in open environments are assumed to be unknown to each other, they interact with the aim of building a trust relationship that will permit the client to gain access to a service offered by the server. This trust relationship is built step by step through the exchange of credentials. Since credentials may certify sensitive information, their release is often regulated, as for services, by access control policies. Usually, these conditions require the counterpart's release of another credential (or set thereof). As an example, a user agrees to release the certificate stating her dialysis condition to a server only if the server proves (through a certificate) to be a medical institution or a pharmacy recognized by the Health Ministry.

To gain access to a service, the client and the server must then find a sequence of certificate exchange, called *strategy*, satisfying the access control policies of both parties. For instance, with reference to the above example, a successful strategy that permits the user to buy the medicine of interest consists of the following steps: (1) the patient sends her request to the pharmacy; (2) the pharmacy answers with a request for a certificate proving that the user has a nephrological disease; (3) the client, in turn, asks the pharmacy for the certificate proving that it is recognized by the Health Ministry; (4) the pharmacy releases to the client the requested certificate; (5) the client then discloses to the pharmacy her dialysis certificate; and (6) finally, the server grants access to the service. Different approaches have been proposed in the literature with the aim of identifying a successful trust negotiation strategy [10,11,13–18] that depends not only on the

policies defined by the parties and on the credentials at their disposal, but also on their choice of disclosure/non-disclosure of their data. As an example, an eager strategy would disclose a credential as soon as the policy regulating its release is satisfied, while a more parsimonious strategy permits the release of a credential only if there exists a *successful strategy* that will finally grant the client access to the service. Given the policies and credentials of the interacting client and server, more than one successful strategy may exist. For instance, with reference to the portfolio in Table 46.1, policy $(type(c) = id) \wedge (c.DoB < 01/01/1994)$ can be satisfied by the client releasing either credential *MyIdCard* or credential *MyPassport*. Although all the successful strategies may seem equivalent, this is generally not true. Both the client and the server may prefer to release a credential over another one because they perceive a different sensitivity level associated with the information that credentials certify. For instance, the client may prefer to release her *id_card* over her *passport*.

Client Privacy Preferences

Given the server request, the client needs to determine which credentials and/or attributes to disclose to satisfy it. This task becomes more difficult if different subsets of credentials and/or attributes in the client portfolio can be used to fulfill the server policy, since the client needs to choose among them. Ideally, the choice should be driven by the sensitivity level that the client perceives for her credentials and attributes, as she will be more willing to disclose less sensitive portfolio components. It is therefore necessary to provide clients with a flexible and effective system that automatically determines the release strategy that better satisfies her privacy preferences. To this purpose, a flexible and expressive model for representing privacy preferences needs to be defined. The following checklist illustrates the main desiderata that a privacy-aware access control system should satisfy (see checklist: An Agenda for Action for a Privacy-Aware Access Control System) [22].

An Agenda for Action for a Privacy-Aware Access Control System

The main desiderata that a privacy-aware access control system should satisfy are as follows (check all tasks completed):

_____**1.** *Fine-grained preference specification.* The privacy preferences associated with attributes and credentials in the client portfolio reflect the sensitivity perceived by the credential owner for the personal information represented by the attribute/credential. The model should support the definition of privacy preferences for each instance of attribute and credential in the client portfolio, meaning that different instances of the same credential type (and credential-dependent attribute) might be associated with different privacy preferences. For instance, with reference to the portfolio in Table 46.1, the client may prefer to release his VISA credit card instead of his AmEx.

_____**2.** *Inheritance of privacy preferences.* To provide flexibility in the definition of privacy preferences and a user-friendly mechanism for their specification, the model should take advantage of the hierarchy of credential types characterizing the client portfolio. When the client portfolio is composed of a huge number of attributes and credentials, it might be difficult for the client to specify a different preference value for each credential and attribute. Privacy preferences associated with abstractions of credential types could, however, be inherited by all its specifications, if not overwritten by a more specific preference value, thus reducing the client overhead. For instance, with reference to the hierarchy of credential types in Figure 46.1 and the portfolio in Table 46.1, the client may specify a single privacy preference associated with credential type *photo_id*, which is automatically inherited by credentials *MyIdCard* and *MyPassport*.

_____**3.** *Partial-order relationship and composition operator.* The domain of privacy preferences should be characterized by a (partial) order relationship $\succcurlyeq$ that permits precisely determining whether a given piece of personal information is more or less sensitive than another. The domain should also be characterized by a composition operator $\oplus$, which permits computing the privacy preference value characterizing the release of a set of attributes and/or credentials. As an example, if the domain of privacy preferences is the set of positive integer numbers, the partial-order relationship could be the "greater than" relationship ($\geq$), while the composition operator could be the sum operator ($+$).

_____**4.** *Sensitive associations.* In different scenarios, the combined release of a set of attributes and/or credentials is considered more (or less) sensitive than the release of each portfolio component singularly taken. For instance, with reference to the portfolio in Table 46.1, the client may consider the combined release of attributes *DoB* and *City* more sensitive than the release of each of the two attributes, since their combination could be exploited to infer the identity of the client [23]. On the other hand, she may value the release of *City* and *Country* less sensitively than the release of the two attributes singularly taken, due to the dependency between the

values of the two attributes. As a consequence, the model should support the definition of a privacy preference value for the combined release of a set of attributes and/or credentials that is different from the result of the combination of the privacy preferences of the items in the set.

5. *Disclosure constraints*. There are situations where the client needs to specify restrictions on the combined release of portfolio components, since she wants to keep the association among a subset of attributes and/or credentials confidential, or limit their combined release. For instance, with reference to the portfolio in Table 46.1, the client may not be willing to release credential *MyDialysis* together with attribute *DoB*, to prevent the server from exploiting this information for data-mining purposes (to analyze the age of people with nephrologic diseases).
6. *Context-based preferences*. The privacy preferences associated with attributes and credentials may vary depending on the context in which their release is requested (and also depending on the requested service and/or on the server providing it). For instance, the client may be more willing to release her dialysis certificate to a pharmacy for buying a medicine than to a hotel for booking a room.
7. *History-based preferences*. The preference of the client toward disclosing one credential (attribute, respectively) over another one may depend on the history of past interactions with the server offering the service. As a matter of fact, if the server already knows the attributes and credentials released by the client during a previous interaction, the client may be more willing to release the same (or a different) set of portfolio components. For instance, with reference to the portfolio in Table 46.1, assume that the client released credential *MyVISA* to a server to buy a service. When interacting again with the same server to buy another service, the client may prefer to use the same credit card, instead of also releasing credential *MyAmEx*.
8. *Proof of possession*. Thanks to novel technologies, clients can release proofs of possession of certificates and proofs of the satisfaction of conditions [20,21]. As a consequence, the model should also permit the client to specify privacy preferences associated with proofs (besides attributes and credentials on which proofs are defined). For instance, with reference to the portfolio in Table 46.1, the client may consider more sensitive the release of her *DoB* than the release of a proof that she is at least 18.
9. *User-friendly preference specification*. The definition of privacy preferences should be easy for the client, who may not be familiar with access control systems. As a consequence, it is necessary to provide clients with interfaces that permit easily defining preferences without introducing inconsistencies.

Server Privacy Preferences

With attribute-based access control, servers regulate access to their services based on the attributes and certificates presented by the requesting client. Upon receiving an access request, the server needs to communicate to the client the policy that she should satisfy to possibly gain access to the service. The access control policy could, however, be sensitive, and the server may not be willing to disclose it completely to the client: While the communication of the complete policy favors the privacy of the client (since she can avoid disclosing her attributes and credentials if they would not satisfy the conditions in the policy), the communication of the attributes involved in the policy only favors the privacy of the server (since the specific conditions are not disclosed). Also, different portions of the same policy may be subject to different confidentiality requirements. For instance, assume that a pharmacy grants clients access to the online medicine purchase service only if the clients' insurance coverage is higher than 10,000 USD and the insurance company is not on the pharmacy black list. The pharmacy might not mind disclosing the fact that only clients with insurance coverage greater than 10,000 USD can access its services, but it does not want to reveal its black list. The system managing the disclosure of server policies should satisfy the following desiderata.

- *Disclosure policy*. The server should be able to define, at a fine-granularity level, how policy release should be regulated.
- *Policy communication*. The communication of the access control policy regulating access to the requested service to the client should guarantee that privacy requirements are satisfied and that the client has enough information to determine the set of attributes and/or credentials she needs to disclose to possibly gain access to the service. It is therefore necessary to define a mechanism that adequately transforms the access control policy before communicating it to the client.
- *Integration with client mechanisms*. The approach designed to regulate policy release should be integrated with the one designed to manage the release of portfolio components at the client side.

Note that in a negotiation process, both the client requesting access to a service and the server providing it possess a portfolio that regulates the disclosure of credentials and attributes composing it, according to their access control policy.

3. COST-SENSITIVE TRUST NEGOTIATION

This section discusses a solution that takes disclosure preferences into consideration in attribute-based access control [24]. The authors propose to associate a *sensitivity costw*(c) with each credential c in the client (and server) portfolio, and with each access control policy p regulating credentials disclosure and access to services. A policy p is defined as a Boolean formula over the credentials in the counterparty's portfolio. A Boolean variable representing credential c in policy p is *true* if c has already been disclosed; it is *false* otherwise. The sensitivity cost associated with credential c (policy p, respectively) models how much the credential's owner (party who defined the policy, respectively) values the release of the credential (policy, respectively) and the disclosure of the sensitive information that the credential certifies. Intuitively, a client (server, respectively) is more willing to disclose credentials (policies, respectively) with lower sensitivity cost, and, vice versa, she prefers to keep credentials (policies, respectively) with high sensitivity cost confidential. For instance, Tables 46.2 and 46.3, respectively, illustrate a client portfolio (server portfolio, respectively). For each credential, the table reports the policy regulating its disclosure, the sensitivity cost of the credential, and the sensitivity cost of its policy. Constant value TRUE is used in policy definition to model the case when the release of a credential is free; that is, it is not regulated by a policy. (The portfolio in Table 46.2 is a simplified version of the portfolio in Table 46.1.)

TABLE 46.2 An Example of Client Portfolio and Policies Regulating its Disclosure.

id(c)	w(c)	Policy p Regulating c	w(p)
MyIdCard	2	TRUE	0
MyPassport	4	TRUE	0
MyCreditCard	10	POS_register	5
MyDialysis	20	pharmacy_register	10
MyInsurance	15	pharmacy_register	10

TABLE 46.3 An Example of Server Portfolio and Policies Regulating its Disclosure.

id(c)	w(c)	Policy *p* regulating c	w(p)
MyPOSRegister	2	TRUE	0
MyPharmacyRegister	5	passport $\vee$ id_card	4

The goal of the client and the server engaging in a negotiation protocol is to *minimize* the sensitivity cost of the credentials and policies exchanged during a successful negotiation strategy. This optimization problem can be formulated as follows [24].

Problem 1: Minimum Sensitivity Cost problem

Let C_s be the set of server credentials and services; P_s the set of policies regulating the disclosure of server credentials and access to services; C_c the set of client credentials; P_c the set of policies regulating the disclosure of client credentials; w:$C_s \cup P_s \cup C_c \cup P_c \rightarrow \mathbb{R}$ the sensitivity cost function; and $s \in C_s$ the service requested by the client. Find an exchange sequence of credentials and policies such that:

1. s is released to the client;
2. the policy regulating the disclosure of each credential released to the counterpart is satisfied before credential release;
3. the sum of the sensitivity costs of released credentials and policies is minimum.

The problem of computing a Minimum Sensitivity Cost strategy is NP-hard [24], and therefore any algorithm that solves it at optimum has exponential cost in the size of its input (the number of credentials and policies in $C_s \cup P_s \cup C_c \cup P_c$). In [24] the authors propose two different heuristic approaches for computing a good (although nonoptimal) solution to the problem. These heuristics have polynomial computational complexity and can be adopted when policies can be freely disclosed and when they are associated with a sensitivity cost, respectively.

Nonsensitive Policies

The solution proposed for the simplified scenario where policies are not associated with a sensitivity cost (they can be freely released) is based on the definition of a *policy graph* modeling the policies regulating credential disclosure at both the client and server side. A policy graph $\boldsymbol{G(V,A,w)}$ is defined as a weighted graph with:

- a vertex $\boldsymbol{v_c}$ for each credential $\boldsymbol{c}$ in $\boldsymbol{C_s} \cup \boldsymbol{C_c}$;
- a vertex v_s for each service s in C_s;
- a vertex v_T for constant value TRUE;

- a vertex v for each disjunction in the policies regulating credential release;
- an edge (v_i, v_j), with v_i and v_j vertexes representing credentials, if the release of the credential represented by v_i is a necessary condition to gain access to the credential represented by v_j;
- an edge (v_i, v_j), with v_i a vertex representing a credential and v_j a vertex representing a disjunction, if v_i is one of the clauses of the disjunction represented by v_j.

The weight of a vertex representing a credential corresponds to the sensitivity cost of the credential it represents, while other vertexes do not have weight. For instance, consider the access control policies in Tables 46.2 and 46.3 and service *MedicineBooking*, regulated by policy $p = dialysis \vee (id\_card \wedge (credit\_card \vee insurance))$. Figure 46.2(a) illustrates the policy graph modeling the access control policies in the system.

The first step of the negotiation process consists in disclosing the policies regulating credential release and access to services at the client and at the server side. This information permits one to correctly build the policy graph. Note that this disclosure is permitted thanks to the assumption that policies are not sensitive in this simplified scenario. The minimum sensitivity cost problem then translates into the equivalent problem of determining a *Minimum Directed Acyclic Graph* for the policy graph, starting at vertex v_T (representing value TRUE) and ending at vertex v_s representing the requested service s. Formally, a Minimum Directed Acyclic Graph is defined as follows.

Definition 1: Minimum Directed Acyclic Graph

Let $G(V, A, w)$ be a policy graph, v_T be the vertex representing value TRUE, and v_s be the vertex representing service s. A directed acyclic graph starting at v_T and ending at v_s is a subgraph $G'(V', A', w)$ of G such that:

1. G' is acyclic;
2. $v_T, v_s, \in V'$;
3. $\nexists(v_i, v_T) \in A', v_i \in V'$;
4. $\nexists(v_s, v_i) \in A', v_i \in V'$;
5. $\forall v_i \in V', \exists v_T | v_i$, where $v_T | v_i$ is a path starting at v_T and ending at v_i;
6. $\forall v_i \in V', \ \forall (v_i, v_j) \in A$, where v_i represents a credential, $(v_i, v_j) \in A', v_j \in V'$;
7. $\nexists G''(V'', A'', w)$ that satisfies all the previous conditions and such that $\sum_{v \in V''} w(v) < \sum_{v \in V'} w(v)$.

It is easy to see that a directed acyclic graph starting at v_T and ending at v_s represents a successful negotiation strategy for service s. Therefore, the minimum sensitivity cost problem and the problem of computing a minimum directed acyclic graph from vertex v_T to vertex v_s are

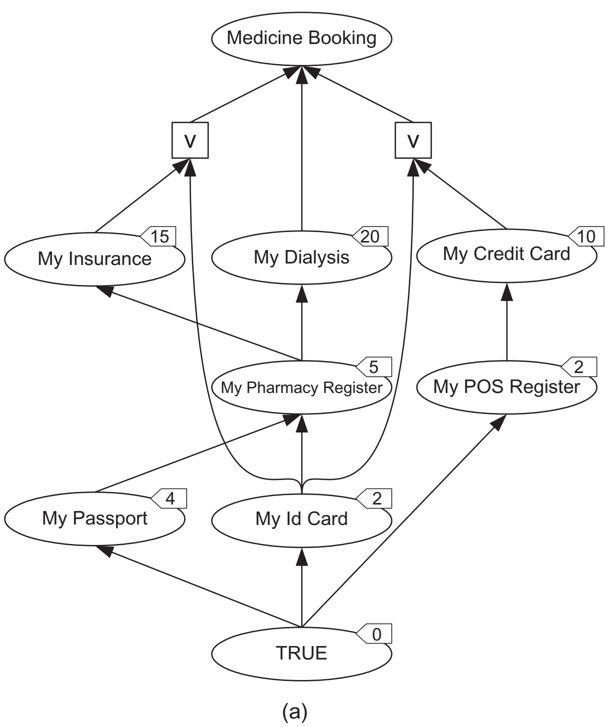

FIGURE 46.2 Policy graph for the policies in Tables 46.2 and 46.3 (a), and Minimum Directed Acyclic graph for the *MedicineBooking* service (b).

equivalent. The heuristic algorithm proposed in [24] is based on a variation of the well-known Dijkstra algorithm [25]. In [24] the authors experimentally prove that the proposed algorithm computes an optimal solution in most cases. For instance, consider the policy graph in Figure 46.2(a) and assume that the client is interested in the *MedicineBooking* service. Figure 46.2(b) illustrates a Minimum Directed Acyclic Graph for the *MedicineBooking* service with cost 14, where the vertexes and edges in the policy graph that also belong to the Minimum Directed Acyclic Graph are in black, while the other vertexes and edge are in gray.

Sensitive Policies

The solution [24] for the more complex scenario where both credentials and policies regulating their release are associated with a sensitivity cost is based on a *greedy strategy* that consists of two steps. During the first step, the interacting parties adopt an eager strategy (each party discloses to the counterpart the name of a credential as soon as the policy for its release is satisfied) to mutually exchange the name and sensitivity cost associated with credentials that could be useful for identifying a successful negotiation strategy with minimum cost. If this first step finds such a strategy, the client and the server start the second step of the protocol, which consists in enforcing the strategy discovered during the first step. For instance, with reference to the policy graph in Figure 46.2 (a), the first step consists of the sequence of releases illustrated in Figure 46.3. First, the client and the server reveal to each other the name and sensitivity cost of credentials whose release is not regulated by a policy, that is, *MyIdCard* and *MyPassport* for the client and *MyPOSRegister* for the server. These releases satisfy the

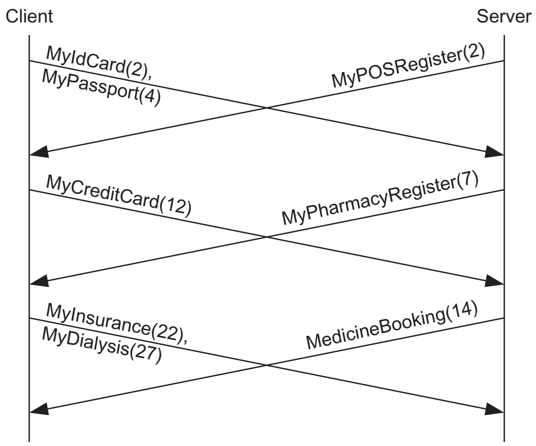

FIGURE 46.3 Sequence of exchanges between the client and the server to determine a successful negotiation strategy.

policy regulating the release of *MyCreditCard* at the client side and *MyPharmacyRegister* at the server side, whose names and sensitivity costs are disclosed. These releases, in turn, satisfy the policies regulating the disclosure of credentials *MyInsurance* and *MyDialysis* at the client side and service *MedicineBooking* at the server side. The exchange then represents a successful negotiation strategy. Note that the edges in Figure 46.3 are labeled with the cumulative sensitivity cost of the negotiation process (*MyCreditCard* is associated with cost $12 = w(MyCreditCard) + w(MyPOSRegister)$). The successful negotiation strategy computed by the first step is enforced during the second step of the protocol. Therefore, the server first discloses credential *MyPOSRegister*, and the client releases *MyIdCard*. When the client receives the credential from the server, she discloses *MyCreditCard*, thus gaining access to the *MedicineBooking* service. The overall sensitivity cost of the strategy is 14.

Open Issues

Although effective, the model and algorithms [24] suffer from some limitations. A first drawback is that the proposed approach assumes that the disclosure of access control policies does not need to be regulated, while policy release may be subject to restrictions. Also, this solution assumes that the objective of a privacy-aware negotiation protocol is to minimize the overall sensitivity cost of credentials and policies disclosed during the negotiation process. However, the goal of the two parties may be different. For instance, with reference to our example, the pharmacy offering the *MedicineBooking* service may not be interested in minimizing the sensitivity cost of the policies and credentials it needs to disclose to offer the service. On the contrary, the patient wants to minimize the sensitivity cost of the credentials she must disclose to the pharmacy. We also note that the model [24] does not satisfy all the desiderata to support privacy preferences in attribute-based access control scenarios. In fact, it only supports the definition of privacy preferences as sensitivity costs, which have a numerical domain characterized by a total order relationship ($\geq$) and by a composition operator ($+$).

4. POINT-BASED TRUST MANAGEMENT

The problem of minimizing the amount of sensitive information disclosed by a trust negotiation protocol [26] is addressed in this section, where the authors propose a *point-based trust management model*. This model assumes that policies regulating access to services and release of credentials are based on the definition of quantitative measures. More precisely, the server associates a

TABLE 46.4 An Example of Points *pt* and Privacy Scores *ps* Associated by the Server and the Client, Respectively, with the Credential in the Client Portfolio.

	id_card	Passport	Credit_card	Dialysis	Insurance
pt	1	1	2	3	2
ps	2	4	10	20	15

number *pt* of *points* with each credential type *t*. This value represents the trustworthiness perceived by the server for the credential issuer (credentials issued by a more reliable party will be associated with a higher number of points and vice versa). To restrict the access to its services, the server then associates a *thresholdthr* with each service. To gain access to a service *s*, the client must disclose a subset of credentials in her portfolio such that the sum of the points of the released credentials is higher than or equal to the threshold fixed by the server for *s*. Analogously, the client associates a *privacy scoreps* with each credential in her portfolio, which represents how much she values the release of the credential to an external server. The higher the privacy value of a credential, the lower the client willingness in its release. As a consequence, a client who is interested in accessing a service *s* must determine a subset of credentials in her portfolio that satisfies the threshold fixed by the server for *s*, while minimizing the privacy score of released credentials. Table 46.4 presents an example of points and privacy scores associated by the server and the client, respectively, to the credentials composing the client's portfolio.

Since the server policy might be considered sensitive, the server does not reveal the threshold associated with its services to the client. Analogously, the client does not reveal to the counterpart the privacy scores she associates with the credentials in her portfolio. As a consequence, when a client requests access to a service, she needs to identify a subset of the credentials in her portfolio that satisfies the server threshold (the access control policy regulating the release of the service) without knowing it and without revealing to the server credentials' privacy scores. More formally, the *Credential Selection* problem is an optimization problem that can be formulated, as discussed in Problem 2 below.

Problem 2: Credential Selection Problem

Let $C = \{c_1, \ldots, c_n\}$ be the set of credentials in the client portfolio; $pt(type(c_i))$ be the points associated by the server with credential type $type(c_i)$, $i = 1, \ldots, n$; $ps(c_i)$ be the privacy score associated by the client with credential c_i, $i = 1, \ldots, n$; s be the service requested by the client; and thr be the release threshold associated with s. Find a subset $D \subseteq C$ of credentials such that:

1. $\sum_{c \in D} pt(type(c)) \geq thr$;
2. $\nexists D' \subseteq C$ s.t. $\sum_{c \in D'} pt(type(c)) \geq thr$ and $\sum_{c \in D'} ps(c) < \sum_{c \in D} ps(c)$.

The first condition states that the subset of credentials in the client portfolio must satisfy the server policy, while the second condition states that the sensitive information disclosed is minimum. For instance, with reference to the points and privacy scores in Table 46.4, let us assume that the server offering service *s* (*MedicineBooking* in our example) defines a threshold $thr = 3$. The release of her *id_card* and of her *credit_card* permits the client to gain access to the service of interest $(pt(id\_card) + pt(credit\_card) = 3 \geq thr)$, while minimizing the overall privacy score of released information $(ps(id\_card) + ps(credit\_card) = 12)$.

Dynamic Programming Algorithm

The Credential Selection problem is NP-hard and can be rewritten into a knapsack problem, where each credential c can be inserted into the knapsack with weight $pt(type(c))$ and value $ps(c)$[26]. Since the knapsack algorithm maximized the value of the items inserted in the knapsack to satisfy its capacity, while the goal of the client is that of minimizing the sensitivity of the credentials necessary to reach the threshold of interest, the solution to the credential selection problem is computed by inserting in the knapsack those credentials that will not be released. Intuitively, the knapsack problem is complementary to our problem and therefore the approach in [26] finds the complementary solution to the Credential Selection problem by exploiting a known dynamic programming algorithm for the knapsack problem [25]. The knapsack capacity KC is computed as the complementary of the threshold fixed by the server with respect to the clients portfolio, that is, $KC = \sum_{c \in C} pt(type(c)) - thr$, which is the difference between the sum of points associated with credential types in the client's portfolio and the threshold fixed by the server to gain access to the service. With reference to the example above, $KC = (1 + 1 + 2 + 3 + 2) - 3 = 6$.

The dynamic programming solution to the knapsack problem is based on the definition of a matrix M with $n + 1$ rows, where n is the number of items that can be inserted into the knapsack (credentials in our scenario), and $KC + 1$ columns. All the cells in the first row and in the first column of the matrix are set to zero ($M[i, 0] = 0$, $i = 0, \ldots, n$, and $M[0, j] = 0$, $j = 0, \ldots, KC$). The value of

the other cells in the matrix is computed according to the following formula:

$$M[i,j] = \begin{cases} M[i-1,j], & j < pt(type(c_i)) \\ \max(M[i-1,j], \\ M[i-1, i-pt(c_i)] + ps(c_i)), & j \geq pt(type(c_i)) \end{cases}$$

The values of the cells in the matrix are computed, in the order, starting from top to bottom and from left to right (by increasing value of i and j, respectively). Each cell in the matrix represents the total value of the knapsack, obtained inserting (a subset) of the items preceding the current element in the matrix without exceeding the knapsack capacity. It is obtained as the current value of the knapsack either including or not including the current element.

Table 46.5 illustrates the matrix computed considering points and privacy scores in Table 46.4. The first row in the matrix represents an empty knapsack. Cells *M*[*id_card*,1],...,*M*[*id_card*,6] in the first row model the insertion of credential *id_card* in the empty knapsack. As a consequence, the knapsack has weight 2. Cell *M*[*passport*,2] is obtained by comparing the solution represented by cell *M*[*id_card*,2] (which models a knapsack including only *id_card*) with the solution *M*[*id_card*,1 ∪]{*passport*} obtained by also inserting credential *passport* into the knapsack. The weight of the two alternative solutions is, respectively, 2 and $2+4=6$. Since $6>2$, *M*[*passport*,2] is set to 6 and it represents a knapsack including credentials *id_card* and *passport*. The other cells in the matrix are computed in the same way.

The optimal solution to the knapsack problem is represented by the value in cell $M[n, KC]$, which represents the value of the knapsack obtained trying to insert all the candidate elements in the knapsack without exceeding its capacity. To determine the elements that belong to the optimal solution, it is necessary to keep track of which item has been inserted at each step. For instance, consider the matrix in Table 46.5, cell *M*[*insurance*,6] = 39 is the sum of the cells in gray in the table; that is, it represent a solution including the credentials *passport*, *dialysis*, and *insurance*. Since the credentials included in the knapsack are not disclosed, the credentials disclosed by the client to gain the access are *id_card* and *credit_card*, which, as already noted, satisfy the threshold fixed by the server for the *MedicineBooking* service while minimizing privacy scores.

TABLE 46.5 An Example of a Dynamic Programming Matrix for the Portfolio in Table 46.4.

	0	1	2	3	4	5	6
0	0	0	0	0	0	0	0

dialysis	0	4	14	20	24	30	34
insurance	0	4	15	20	29	35	39

The traditional dynamic programming algorithm described above for the knapsack problem assumes that the client knows the points assigned by the server to credential types (or that the server knows the privacy scores that the client associates with the credentials in her portfolio). Since this assumption does not hold in the considered scenario, in [26] the authors propose to enhance the basic algorithm to permit the client and the server to interact with each other for computing a solution to the knapsack problem without the need for the client and the server to reveal to each other their secret parameters. The proposed solution consists of a secure two-party dynamic-programming protocol, which relies on homomorphic encryption to provide privacy guarantees to sensitive information [27,28].

Open Issues

The model and algorithm introduced in [26] suffer from different shortcomings. First, the client and the server must share, as common knowledge, the set of possible credentials on which the negotiation process should be based. Such knowledge may, however, put the privacy of the server policy at risk. The proposed model also assumes that the access control policy defined by the server consists of a threshold value, but in many real-world scenarios the server needs to define more expressive policies. Furthermore, the focus of the proposal, as well as the model in [24], is more on the negotiation process than on the management of the privacy preferences of the interacting parties. The solution in [26], however, represents an important step toward defining a privacy-aware access control model, even if it does not satisfy all the desiderata. In fact, this approach only supports the definition of privacy preferences as privacy scores, which have a numerical domain characterized by a total order relationship ($\geq$) and by a composition operator ($+$).

5. LOGICAL-BASED MINIMAL CREDENTIAL DISCLOSURE

The solutions in [24,26] are based on the assumption that privacy preferences can be expressed as numerical values, defined over a domain characterized by a total order relationship and an additive operator. While this assumption permits one to easily integrate privacy preferences with

traditional negotiation processes, the usability of the resulting system may be limited. In fact, it might not be easy for the final user to express her privacy preferences through numeric values, also because the adoption of numeric preference values may cause unintended side effects (dominance relationships are not explicitly defined but are implied by the values assigned to the portfolio components). To overcome these limitations, in [29], the authors propose adopting *qualitative* (instead of quantitative) preference values. The proposed solution is based on the assumption that credentials are singleton (certify one attribute only) and that the policy defined by the server is publicly available. The goal of the approach is to determine, among the successful negotiation strategies, the one that better suits the client preferences (i.e., the set of credentials that minimizes the amount of sensitive information disclosed to the server to gain access to the requested service). When the number of successful strategies is limited, the client can explicitly choose the one she prefers. However, when the number of credentials in the client portfolio increases and the server policy becomes complex, the number of successful trust negotiation strategies may grow quickly. For instance, assume that the client portfolio is composed of credentials {*Name*, *DoB*, *City*, *VISANum*, *VISALimit*, *AmExNum*, *AmExLimit*, *Insurance*, *InsCoverage*, *Dialysis*}, and that the policy regulating access to the *MedicineBooking* service is ((*Name* ∧ (*DoB* ∨ *City*) ∨ *Dialysis* ∨ *Insurance*) ∧ ((*VISANum* ∧ *VISALimit*) ∨ (*AmExNum* ∧ *AmExLimit*) ∨ (*InsCoverage* ∧ *DoB*)). There are 12 strategies that satisfy the access control policy. It is therefore necessary to define a mechanism that permits exploiting qualitative disclosure preferences defined by the client to limit the number of strategies among which she is explicitly asked to choose.

Qualitative Preferences

Given the set $C = \{c_1, \ldots, c_n\}$ of credentials in the client portfolio, the release of a subset of credentials is modeled as a binary n-dimension vector D, where $D[i] = 1$ if c_i is released and $D[i] = 0$; otherwise, $i = 1, \ldots n$. For instance, with reference to the previous example, Table 46.6 summarizes the subsets of portfolio credentials satisfying the policy regulating service *MedicineBooking*. Disclosure D_1 represents the release of {*Name*, *DoB*, *VISANum*, *VISALimit*}.

The model [29] proposed permits one to specify privacy preferences at different granularity levels. Dominance relationship $\succ_i$ defines disclosure preferences for credential c_i. Usually, credential-level preferences state that $0 \succ_i 1$, $i = 1, \ldots n$, meaning that the client prefers not to disclose credential c_i. To compare the disclosure of different subsets of credentials in the client portfolio, credential-level preferences are composed according to the *Pareto composition* operator $\succ_P$. A disclosure set D_i dominates, according to the Pareto composition, a disclosure set D_j if, for each credential c_l in the portfolio, either $D_i[l] \succ_l D_j[l]$ or $D_i[l] =_l D_j[l]$, meaning that D_i releases a proper subset of the credentials in D_j. For instance, consider the disclosure sets in Table 46.6, $D_3 \succ_P D_6$ since $D_3[DoB] \succ_{DoB} D_6[DoB]$, that is, $D_6 = D_3 \cup \{\text{DoB}\}$.

TABLE 46.6 Disclosure Strategies that Satisfy the Access Control Policy of Service *MedicineBooking*.

	Name	DoB	City	VISANum	VISALimit	AmExNum	AmExLimit	Insurance	InsCoverage	Dialysis
D_1	1	1	0	1	1	0	0	0	0	0
D_2	1	1	0	0	0	1	1	0	0	0
D_3	1	1	0	0	0	0	0	0	1	0
D_4	1	0	1	1	1	0	0	0	0	0
D_5	1	0	1	0	0	1	1	0	0	0
D_6	1	1	1	0	0	0	0	0	1	0
D_7	0	0	0	**1**	**1**	0	0	0	0	**1**
D_8	0	0	0	0	0	**1**	**1**	0	0	**1**
D_9	0	1	0	0	0	0	0	0	**1**	**1**
D_{10}	0	0	0	**1**	**1**	0	0	**1**	0	0
D_{11}	0	0	0	0	0	**1**	**1**	**1**	0	0
D_{12}	0	**1**	0	0	0	0	0	**1**	**1**	0

The most interesting kind of preferences modeled by the solution [29] is represented by *amalgamated preferences*, which compare the release of sets of credentials that are not related by a subset−containment relationship. Amalgamated preferences are of the form $c_i \rightarrow c_j$, meaning that the client prefers to release credential c_i over credential c_j. This preference defines a dominance relationship, denoted $\succ_{\{i,j\}}^{(1,0)(0,1)}$, among disclosure sets. More formally, disclosure set D_k dominates, according to amalgamated preference $c_i \rightarrow c_j$, disclosure set D_l if $D_k[i] = 1$, $D_k[j] = 0$, $D_l[i] = 0$, $D_l[j] = 1$, and $D_k[x] = D_l[x]$, for all $x \neq i$, $x \neq j$. For instance, consider the disclosure sets in Table 46.6 and amalgamated preference *Insurance* → *Dialysis*, then $D_{10} \succ_{\{Insurance,Dialysis\}}^{(1,0)(0,1)} D_7$ since they both disclose credentials *VISANum* and *VISALimit*, but D_{10} releases *Insurance* while D_7 releases *Dialysis*. Analogously, $D_{11} \succ_{\{Insurance,Dialysis\}}^{(1,0)(0,1)} D_8$ and $D_{12} \succ_{\{Insurance,Dialysis\}}^{(1,0)(0,1)} D_9$. Note that the binary subvectors on the top of the dominance operator can be any pair of binary subvectors of the same length. Amalgamated preferences can be conveniently represented through a graph, whose vertexes model credentials and whose edges represent disclosure preferences among them. Note that, to avoid inconsistencies in the definition of privacy preferences, the disclosure graph must be acyclic. The model [29] also permits specifying conditions associated with preferences, meaning that a dominance relationship holds only if the associated condition is satisfied (e.g., only if a given credential has already been disclosed). For instance, the client may prefer to release credential *Insurance* over her *Name* if credential *InsCoverage* has already been released (since the server is aware of the fact that the client has subscribed an insurance). These conditions are graphically represented by labels associated with the edges of the preference graph. Figure 46.4 illustrates an example of a graph representing amalgamated preferences for the portfolio in our example. Consider the disclosure sets in Table 46.6, according to the preferences in the graph, $D_1 \succ_{\{DoB,City\}}^{(1,0)(0,1)} D_4$ and $D_2 \succ_{\{DoB,City\}}^{(1,0)(0,1)} D_5$ since the disclosure of *DoB* is preferred to the disclosure of *City*. Also, $D_{12} \succ_{\{Insurance,Name\}}^{(1,0)(0,1)} D_3$ since credential *InsCoverage* has already been released, and therefore the client prefers to release *Insurance* instead of *Name*.

Both the dominance relationship defined by the Pareto composition and the dominance relationships induced by amalgamated preferences permitta comparison of disclosure sets that differ only for the release of the subset of credentials on which the dominance relationship has been defined. However, it may happen that two disclosure sets cannot be compared considering one dominance relationship only, but they can be compared combining two or more disclosure preferences. For instance, consider the graph in Figure 46.4 and the disclosure sets in Table 46.6. Disclosure sets D_1 and D_2 cannot be directly compared, but it is immediate to see that D_1 dominates D_2 by combining amalgamated preferences *VISANum*→*AmExNum* and *VISALimit*→*AmExLimit*. In fact, D_1 discloses the attributes of the VISA credit card, while D_2 discloses the attributes of the AmEx credit card. In [29] the authors propose incrementally composing certificate-level and amalgamated preferences. The transitive closure of all the preferences in the system permits defining a *complete preference relationship*, denoted $\succ\succ$, which summarizes all the preference relationships expressed by the client. As a consequence, given the access control policy p regulating the release of the service requested by the client, the approach in [29] permits one to limit the set of successful disclosure strategies among which the client needs to choose. In fact, the choice can be restricted to the *optimal disclosure sets*—that is, to the sets of credentials in the client portfolio that satisfy p and that are not dominated by another disclosure set that satisfies p. More formally, the set of optimal disclosure sets is defined as follows [29].

Definition 2: Optimal Disclosure Sets

Let $C = \{c_1, \ldots, c_n\}$ be the set of credentials in the client portfolio; s the service requested by the client; p the access control policy regulating the release of s; $\mathscr{D} = \{D_1, \ldots, D_m\}$ the set of disclosure sets that satisfy p, with $D_i \subseteq C$, $i = 1, \ldots, n$; and $\succ\succ$ a complete preference relationship over C. An optimal disclosure set $\mathscr{D}_{\succ\succ}$

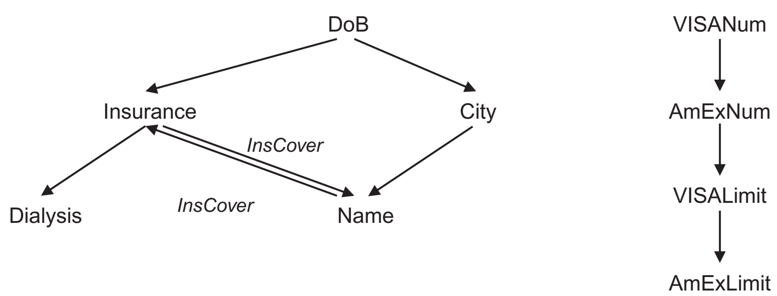

FIGURE 46.4 An example of a set of amalgamated preferences.

of $\mathscr{D}$ wrt $\succ\succ$ is defined as: $\mathscr{D}_{\succ\succ} = \{D \in \mathscr{D} | \nexists D' \in \mathscr{D}, D' \succ\succ D\}$.

The disclosure sets in $\mathscr{D}_{\succ\succ}$ are optimal and cannot be compared with respect to the disclosure preferences defined by the client (i.e., they are equivalent according to client preferences). To finally decide which set of credentials to disclose to the server, the client needs to choose, among the negotiation strategies in $\mathscr{D}_{\succ\succ}$, the one she prefers to disclose. For instance, with reference to the disclosure sets in Table 46.6 and the preferences in Figure 46.4, $\mathscr{D}_{\succ\succ} = \{D_1, D_{10}, D_{12}\}$.

Open Issues

The solution proposed in [29] has the great advantage over the approaches of modeling and managing qualitative preferences. In fact, it permits specifying privacy preferences at the attribute granularity, and it defines a partial-order relationship and different composition operators over the domain of privacy preferences, therefore making it easy for the client to use. However, it still needs to be enhanced to comply with all the desiderata that a privacy-aware access control system should satisfy. The main shortcoming from which the proposal in [29] suffers is that it requires client intervention in the choice of the set of credentials to disclose among the successful strategies in the optimal set. Also, the proposed model assumes that each credential in the client portfolio certifies one attribute only, while often credentials include a set of attributes that cannot be singularly released (atomic credentials).

6. PRIVACY PREFERENCES IN CREDENTIAL-BASED INTERACTIONS

The first solution that formally models the client portfolio to permit the client to specify fine-grained privacy preferences, as well as constraints on the disclosure of portfolio components, has been proposed in [19]. One of the main advantages of the portfolio modeling in [19] is that it permits one to represent both atomic and nonatomic credentials, declarations, and the attributes composing them, clearly distinguishing between credential-dependent and credential-independent attributes. As a consequence, this modeling permits one to easily associate privacy preferences with each credential and attribute in the client portfolio. More precisely, the client portfolio is modeled as a bipartite graph $G(V_C \cup V_A, E_{CA})$, with a vertex for each credential and each attribute in the portfolio and an edge connecting each credential to the attributes it certifies. It is important to note that each credential-independent attribute is represented by a vertex in G, while each credential-dependent attribute is represented by several vertexes (one for each credential certifying it). For

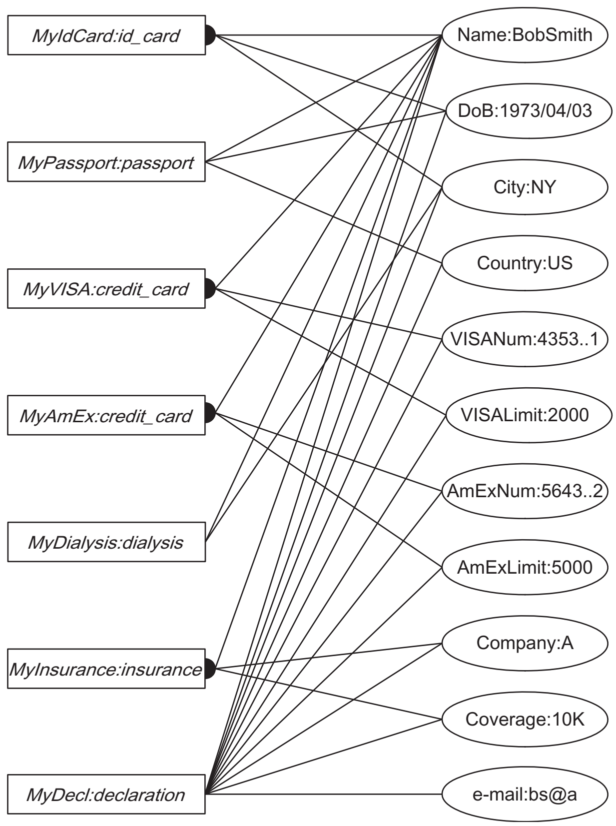

FIGURE 46.5 Portfolio graph of the portfolio in Table 46.1.

instance, Figure 46.5 illustrates the graph representing the portfolio in Table 46.1, where we distinguish atomic credentials by attaching all the edges incident to the vertex representing the credential to a black semicircle. The label of vertexes representing credentials is of the form *id*:type, where *id* is the identifier of the credential and *type* is its type. The label of vertexes representing attributes is of the form `name`:value.

Sensitivity Labels

The client can define her privacy preferences at a fine-granularity level by associating a *sensitivity label* with each credential and attribute (or combinations thereof) in her portfolio. These labels represent how much the client values the disclosure of the portfolio components. The domain Λ of sensitivity labels can be any set of values characterized by a partial-order relationship $\succcurlyeq$, and a composition operator $\oplus$. This generic definition of sensitivity labels captures different methods for expressing preferences. For instance, sensitivity labels could be positive integer values, where the order relationship $\succcurlyeq$ is the traditional $\geq$ relationship and the composition operator can either be the sum $(+)$ or the maximum. In the example, for simplicity, we will consider numerical sensitivity

labels. Labeling function λ associates a sensitivity label in Λ with each credential c, with each attribute a in the client portfolio, and possibly with subsets thereof. Figure 46.5 illustrates the portfolio graph in Figure 46.5, extended by associating each vertex with its sensitivity label and by including new vertexes that represent associations and disclosure constraints. The semantics of the sensitivity labels associated with portfolio components can be summarized as follows.

- $\lambda(a)$: defines the sensitivity of attribute a singularly taken and reflects how much the client values its disclosure. For instance, with reference to the portfolio graph in Figure 46.5, $\lambda(\mathit{VISANum}) \geq \lambda(\mathit{DoB})$ since the client considers the number of her VISA more sensitive than her date of birth.
- $\lambda(c)$: defines the sensitivity of the *existence* of credential c. This label reflects how much the client values the additional information carried by the credential itself, independently from the attributes it certifies. For instance, with reference to the portfolio graph in Figure 46.5, $\lambda(\mathit{MyDialysis})$ reflects the sensitivity associated by the client with the credential certifying her nephrological disease, independently from the fact that this credential also certifies attributes *Name* and *City*. Clearly, the existence of the credential itself has a sensitivity that goes beyond the demographical information it certifies.

The sensitivity label associated with the combined release of a set of credentials and attributes generally corresponds to the composition through operator $\oplus$ of the sensitivity labels of each portfolio component in the released set. For instance, the release of atomic credential *MyIdCard* has sensitivity label $\lambda(\mathit{MyIdCard}) \oplus \lambda(\mathit{Name}) \oplus \lambda(\mathit{DoB}) \oplus \lambda(\mathit{City})$. There are, however, cases where the combined release of some portfolio components may cause a higher or lower information disclosure than the sensitivity label obtained composing the labels of the released credentials and attributes. To capture these situations, the model in [19] permits the client to specify sensitivity labels for subsets of portfolio components, representing how much the client values the release of the *association* of their values. The sensitivity labels of associations must then be considered when composing the sensitivity labels of the attributes and/or credentials in the association. Graphically, associations are represented by additional vertexes in the portfolio graph, connected to the attributes and/or credentials composing the associations. In particular, the following two kinds of associations are modeled.

- *Sensitive views* model situations where the combined release of a set of portfolio components carries *more* information than the composition of the sensitive labels of its components. For instance, with reference to the portfolio graph in Figure 46.5, $\lambda(\{\mathit{DoB}, \mathit{City}\}) = 4$ models the additional sensitivity carried by the combined release of the two attributes.
- *Dependencies* model situations where the combined release of a set of portfolio components carries *less* information than the composition of the sensitive labels (see Figure 46.6) of its components. For instance, with reference to the portfolio graph in Figure 46.5, $\lambda(\{\mathit{City}, \mathit{Country}\}) = -2$ represents the sensitivity to be removed when the two attributes are released together, since the knowledge of the *City* where a user leaves permits one to easily infer her *Country*. The sensitivity label associated with a dependency $\mathscr{A} = \{c_i, \ldots, c_j, a_k, \ldots, a_l\}$ can assume any value, provided the sensitivity label of the combined release of all the credentials and attributes in $\mathscr{A}$ dominates the sensitivity label of the most sensitive element in $\mathscr{A}$ ($\lambda(c_i) \oplus \ldots \oplus \lambda(c_j) \oplus \lambda(a_k) \oplus \ldots \oplus \lambda(a_l) \oplus \lambda(\mathscr{A}) \succcurlyeq \max(\lambda(x),\ x \in \mathscr{A})$).

In addition to sensitivity labels associated with credentials, attributes, and subsets thereof, the client may need to specify disclosure constraints that cannot be expressed through sensitivity labels. To this purpose, in [30] the authors extend the original model introduced in [19] with the following two kinds of constraints.

- *Forbidden views* represent subsets of portfolio components whose combined release is prohibited. For instance, with reference to the portfolio graph in Figure 46.5, forbidden view $\{\mathit{DoB}, \mathit{MyDialysis}\}$ prevents the combined release of attribute *DoB* and credential *MyDialysis* and is graphically represented by a cross-shaped vertex connected with the attribute and credential in the constraint.
- *Disclosure limitations* represent subsets of portfolio components characterized by restrictions of the form *at most n* elements in the set can be jointly disclosed. For instance, with reference to the portfolio graph in Figure 46.5, disclosure limitation $\{\mathit{Name}, \mathit{City}, \mathit{Country}, \textit{e-mail}\}_2$ permits release at most of two attributes in the set and is graphically represented by a cross-shaped vertex with label 2 and connected with all the attributes in the set.

Disclosure

Given the client portfolio, it is important to note that not all the subsets of portfolio components represent a valid disclosure; that is, not all the sets of credentials and attributes can be communicated to the server to gain access to the requested service. First, a subset QUOTE of portfolio components represents a *disclosure* only if it satisfies the following three conditions.

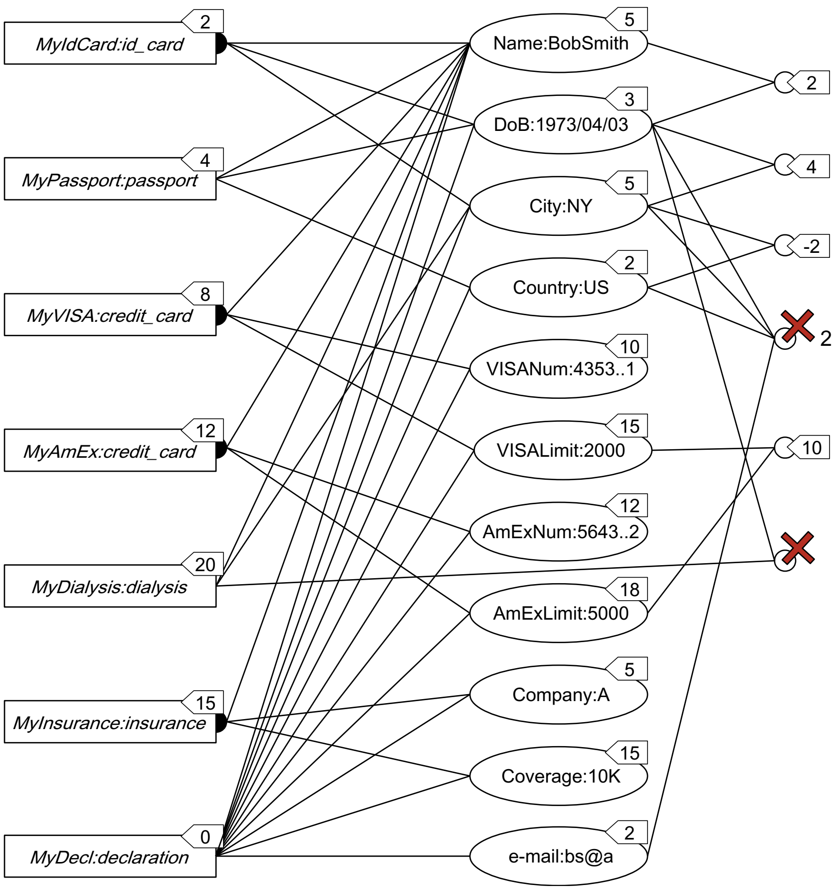

FIGURE 46.6 Portfolio graph extended with sensitivity labels, associations, and constraints.

1. *Certifiability*: Each disclosed attribute is certified by at least a credential, whose existence is disclosed as well ($\forall a \in D, \exists c \in D s.t.\ a \in attributes(c)$).
2. *Atomicity*: If an attribute certified by an atomic credential is disclosed, all the attributes in the credential are disclosed ($\exists c \in D s.t. c$ is atomic, $\forall a \in attributes(c), a \in D$).
3. *Association exposure*: If all the attributes and/or credentials composing an association are disclosed, then the association itself is disclosed ($\forall x \in \mathscr{A}, x \in D$ then $\mathscr{A} \in D$).

These conditions permit one to easily take into account both atomic and nonatomic credentials, as well as associations, in the computation of the sensitivity label characterizing the disclosure of a set of credentials and attributes. For instance, consider the portfolio graph in Figure 46.5. An example of disclosure D is represented in Figure 46.7 (a), where released elements are reported in black while nonreleased elements are reported in gray. Figure 46.7(b) represents instead a subset of the portfolio components that does not represent a disclosure, since it violates the above properties. The *sensitivity* of a disclosure D is computed by composing the sensitivity label of all the credentials, attributes, and associations composing it. For instance, the sensitivity of the disclosure in Figure 46.7(a) is $\lambda(D) = \lambda(MyPassport) + \lambda(MyVISA) + \lambda(MyDecl) + \lambda(Name) + \lambda(DoB) + \lambda(VISANum) + \lambda(VISALimit) + \lambda(e\text{-}mail) + \lambda(\{Name, DoB\}) = 4 + 8 + 0 + 5 + 3 + 10 + 15 + 2 + 2 = 49$. A disclosure is said to be *valid* if it does not violate disclosure constraints. Only valid disclosures can be released. For instance, the disclosure in Figure 46.7(a) is valid, while the one in Figure 46.7(c) is not valid since it violates forbidden view $\{DoB, MyDialysis\}$.

Given the server policy p regulating the disclosure of the service of interest, it is necessary to determine a *minimum disclosure* (a valid disclosure with minimum sensitivity label) satisfying p. The authors [19] assume that server policies are formulated as Boolean formulas composed of terms of the form $t.\{a_i, \ldots, a_j\}$ in disjunctive normal form. A clause $t.\{a_i, \ldots, a_j\}$ in the server policy requires the disclosure of a credential c of type t that certifies attributes $\{a_i, \ldots, a_j\}$. A valid disclosure D satisfies a term $t.\{a_i, \ldots, a_j\}$ if $\exists c \in D s.t.\ type(c) \preceq_{isa} t$ and $\{a_i, \ldots, a_j\} \subseteq attributes(c)$. For instance, assume that the policy regulating access to the *MedicineBooking* service is $id.\{Name\} \wedge credit\_card.\{Name, Number, Limit\} \wedge *$.

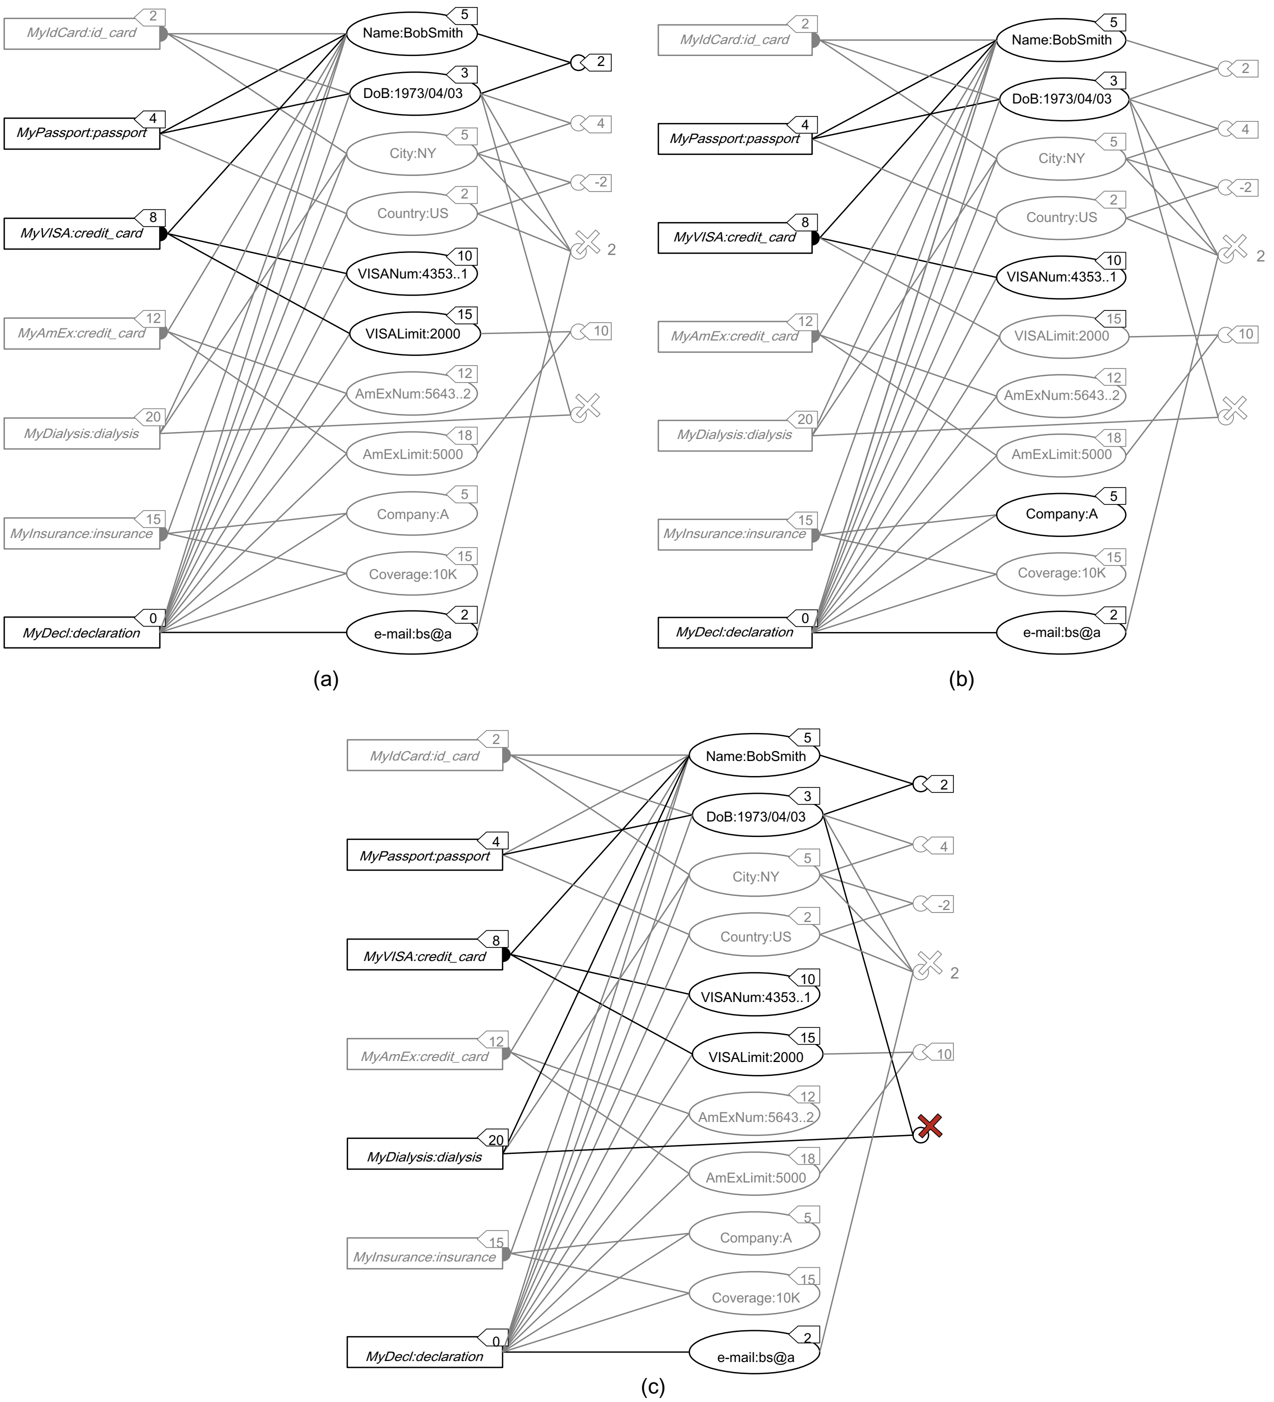

FIGURE 46.7 An example of valid disclosure (a), arbitrary subset of portfolio elements (b), and nonvalid disclosure (c).

{*DoB*,*e-mail*}. The disclosure in Figure 46.7(a) satisfies the policy and grants the client access to the requested service: Term *id*.{*Name*} is satisfied by the release of attribute *Name* from credential *MyIdCard*; term *credit_card*.{*Name*,*Number*,*Limit*} is satisfied by the release of atomic credential *MyVISA*; and term *.{*DoB*,*e-mail*} is satisfied by the release of attribute *DoB* from credential *MyIdCard* and by the declaration of attribute *e-mail*. Formally, the minimum disclosure problem can then be formulated, as discussed in Problem 3 below.

Problem 3: Minimum Disclosure Problem

Let $C = \{c_1, \ldots, c_n\}$ be the set of credentials in the client portfolio; $A = \{a_1, \ldots, a_m\}$ the set of attributes in the client portfolio; $(T, \preceq_{isa})$ the hierarchy of credential types; A the set of sensitive associations; F the set of forbidden views; L the set of disclosure limitations; λ the labeling function; and p the server policy. Find a subset $D \subseteq C \cup A$ such that:

1. $\forall a \in D, \exists c \in D s.t.\ a \in attributes(c)$ (certifiability);
2. $\exists c \in D s.t. c$ is atomic, $\forall a \in attributes(c), a \in D$ (atomicity);
3. $\forall x \in \mathscr{A}, x \in D$ then $\mathscr{A} \in D$ (association exposure);
4. (forbidden views satisfaction);
5. $\forall l_i \in L, \nexists l' \subseteq D s.t. |l'| \geq i$, with i the threshold fixed by constraint l_i (disclosure limitation satisfaction);
6. $\exists$ a clause $t_1.\{a_{i1}, \ldots, a_{j1}\} \wedge \ldots \wedge t_l.\{a_{il}, \ldots, a_{jl}\}$ in p such that for each term $t.\{a_i, \ldots, a_j\}$ in the clause, $\exists c \in D s.t. type(c) \preceq_{isa} t$ and $\{a_i, \ldots, a_j\} \subseteq attributes(c)$ (policy satisfaction);
7. $\nexists D'$ satisfying all the conditions above and such that $\lambda(D) \succ \lambda(D')$.

For instance, the disclosure in Figure 46.7(a) represents a minimal disclosure for our example. The problem of computing a minimal disclosure is NP-hard [19]. In [19] the authors propose a graph-based heuristic algorithm to compute a minimal disclosure (a disclosure that, though not minimal, has a low sensitivity label). In [30] the authors define a modeling of the problem as an instance of the Max-SAT problem, and use Max-SAT solvers to compute an optimum solution in a limited computational time.

The model in [19] has been extended in [31] to permit the client to complement her privacy preferences with *context-based restrictions* that limit the disclosure of credentials on the basis of the context of her request. In the same paper, the authors also propose to take the *history* of past interactions into account in the choice of the set of credentials and attributes to disclose for gaining access to the requested service.

Open Issues

The modeling of the client portfolio proposed in [19] permits the client to specify sensitivity labels at the attribute granularity level and to take advantage of new constructs for taking sensitive associations and disclosure constraints into consideration in the choice of the set of portfolio components to disclose. This approach, however, leaves space for further improvements. Sensitivity labels modeling privacy preferences may not be easy to define for final users. In fact, as already noted in [29], it is hard to associate a quantitative value with each portfolio component (and possible subset thereof), while it would be easier to define a partial-order relationship between subsets of portfolio components.

7. FINE-GRAINED DISCLOSURE OF SENSITIVE ACCESS POLICIES

In [32], the authors address the problem of regulating the disclosure of access control policies by proposing a model that permits the server to specify a *disclosure policy* regulating if and how an access control policy should be communicated to the client. To this purpose, the approach in [32] models access control policies as *policy trees*. Policy tree $T(N)$ representing policy p has a node for each operator, attribute, and constant value in p. The internal nodes of the tree represent operators, whose operands are represented by the subtrees rooted at its children. For instance, Figure 46.8 represents the policy tree of $p = (type(c_1) = credit\_card \wedge c_1.Limit > 1{,}000) \vee (type(c_2) = insurance \wedge c_2.Company \neq$ 'A' $\wedge\ c_2.Company \neq$ 'B').

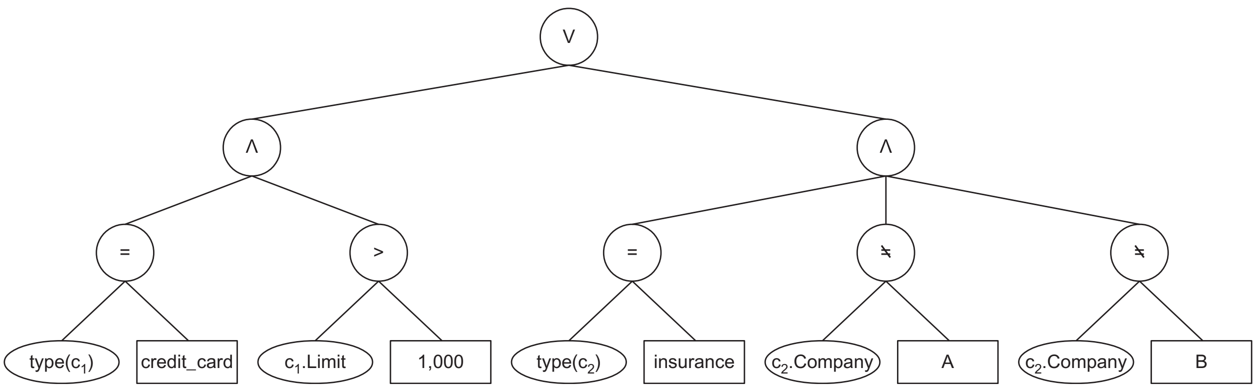

FIGURE 46.8 An example of policy tree.

Disclosure Policy

The disclosure policy regulating the release of a policy p to a client regulates the visibility of each node in the policy tree T(N). The disclosure policy is formally defined as a coloring function $\gamma{:}N \rightarrow \{green, yellow, red\}$ that associates with each node n in the policy tree a color in the set {*green*, *yellow*, *red*}, thus obtaining a *colored policy tree*$T(N, \gamma)$. The semantics of the colors, with respect to the client visibility of a node, can be summarized as follows:

- *green*: The node is released.
- *yellow*: The label of the node is removed (the operator, attribute, or constant value it represents) before its release, while its presence in the tree and its children are preserved.
- *red*: The label of the node is removed and possibly also its presence in the tree.

As an example, Figure 46.9 illustrates a possible coloring regulating the disclosure of the policy tree in the figure. In the figure, QUOTE nodes are white, QUOTE nodes are gray, and QUOTE nodes are black.

Although the server can decide to associate an arbitrary color with each node in the tree, a disclosure policy is *well defined* if it is meaningful. More precisely, a disclosure policy is well defined if it satisfies the following conditions.

1. If a leaf node representing a constant value is *green*, then its sibling (which represents an attribute) is *green* and its parent (which represents an operator) is not *red*.
2. If a node representing an operator is *green*, at least one of its children must be either *green* or *yellow*.
3. The nodes in a subtree representing a condition on credential type must be either all *green* or all *red*.

Figure 46.10 presents an example of non−well-defined coloring for the policy tree in Figure 46.9. In fact, since only node ‘A’ is *green* in the subtree representing condition $c_2.Company \neq$ ‘A’, the server would disclose value ‘A’ instead of the condition. Analogously,

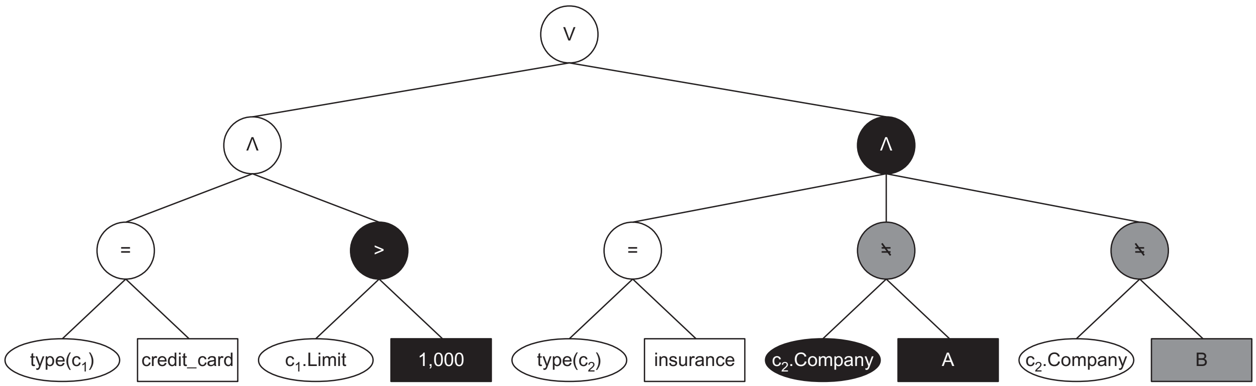

FIGURE 46.9 An example of coloring for the policy tree.

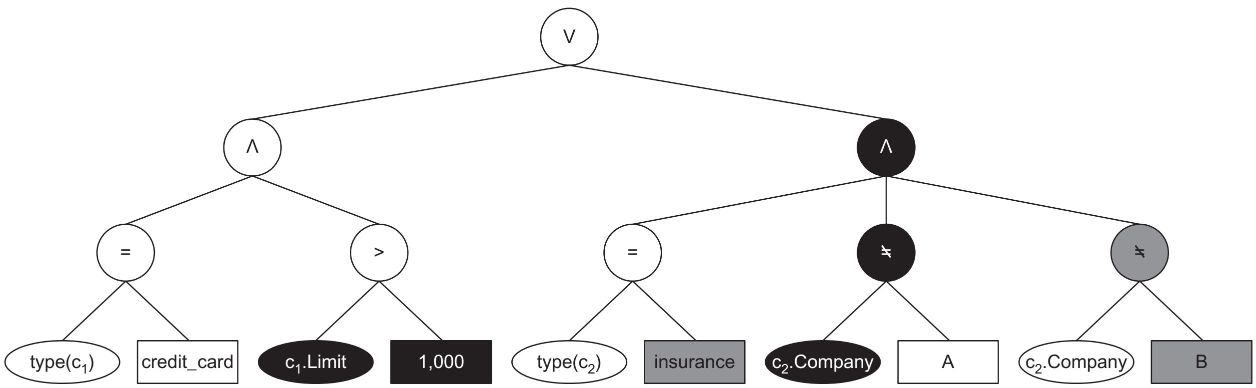

FIGURE 46.10 An example of non−well-defined colored policy tree.

only node $>$ is *green* in the subtree of condition $c_1.Limit > 1{,}000$, and the server would disclose the operator $>$ only to the client. Finally, node *insurance* is *yellow* in the sub-tree of condition $type(c_2) = insurance$, while the other nodes are *green*. The disclosed condition would then only release operand $type(c_2)$ and operator $=$, which does not give the client any information to possibly gain access to the service.

Policy Communication

When the client sends a request for accessing a service to the server, the server transforms its access control policy into a client policy view according to the disclosure policy. The colored policy tree $T(\mathrm{N}, \gamma)$ regulating policy disclosure is therefore transformed into an equivalent *client policy tree view* by: (1) removing the label of *yellow* and *red* nodes; (2) removing unnecessary *red* leaves; and (3) collapsing internal *red* nodes in a parent–child relationship in a single *red* node. To this purpose, the server visits the tree following a post-order strategy and applies, in the order, the following three classes of transformation rules.

- *Prune rules*. These rules remove unnecessary leaf nodes. Two kinds of prune rules can be applied on an internal node n whose children are leaf nodes.
  - *Red predicate rule*. If n is *red*, all its *red* children are removed. For instance, consider the colored policy tree in Figure 46.10; according to this rule, the node representing constant value 1,000 is removed.
  - *Red children rule*. If all the children of n are *red*, they are removed and the color of node n is set to *red*. For instance, consider the colored policy tree in Figure 46.10; according to this rule, the nodes representing attribute *Company* and constant value 'A' in condition ($c_2.Company \neq$ 'A') are removed. Also, the color of the node representing operator $\neq$ is set to red.
- *Collapse rule*. This rule operates on internal *red* nodes and removes their non-leaf *red* children. For instance, consider the colored policy tree in Figure 46.9; the node representing operator $\neq$ in condition ($c_2.Company \neq$ 'A') is removed since its parent (i.e., the second child of the root node) is *red*.
- *Hide label rule*. This rule removes the labels of *yellow* and *red* nodes.

Figure 46.11 illustrates the client policy tree view obtained by applying the transformation rules described above to the colored policy tree in Figure 46.10.

The disclosure of a client policy tree view may be meaningless for the client, since it may not represent in a "fair way" the server access control policy [32]. Intuitively, a client policy tree view fairly represents the server policy if it includes at least a subset of attributes that permit the access control policy evaluation. In fact, in this case, the client can decide whether to release the requested attributes to possibly gain access to the service of interest. Clearly, the server should disclose only fair policies. For instance, the policy view represented by the tree in Figure 46.7 is fair, since all the attributes and credential types in the original policy are preserved in the client view. The client can decide whether to release either one of her credit cards or her insurance to possibly gain access to the *MedicineBooking* service.

Open Issues

The solution proposed in [32] to protect the confidentiality of access control policies, while permitting the client-server interaction in open environments, is effective and permits the definition of disclosure restrictions at a fine granularity level. However, this proposal represents only a first step in the definition of an effective system

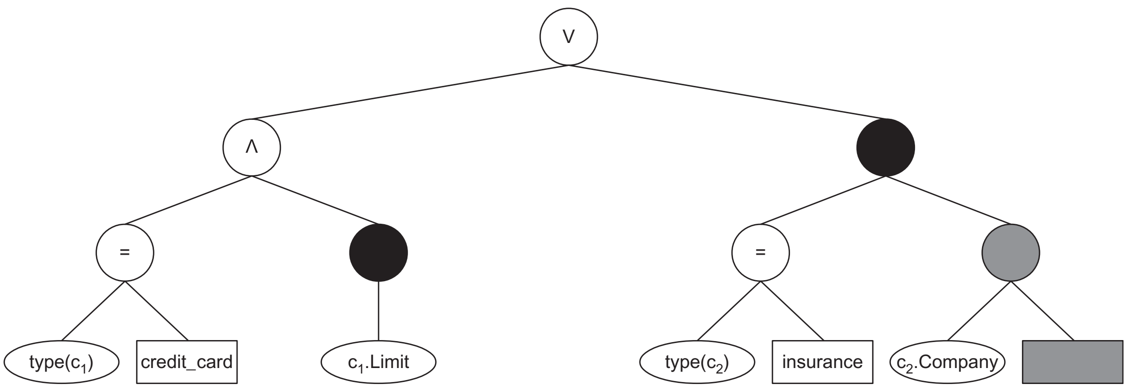

FIGURE 46.11 Policy tree view of the colored policy tree.

regulating policy disclosure. In fact, the proposed model permits one to check whether a disclosure policy generates a fair client policy tree view, but it does not propose an approach for possibly revising the disclosure policy when the client policy tree view is not fair (and therefore prevents the definition of a successful negotiation strategy). Also, the model could be extended to consider the disclosure of proofs of possession and/or proofs of satisfaction of condition.

8. OPEN ISSUES

The enforcement of access privileges in open environments, taking into account both client privacy preferences and policy confidentiality requirements still presents different open issues that need to be addressed.

- *Inheritance of privacy preferences*. Most of the solutions proposed in the literature assume that the client associates a preference with each credential and/or attribute in her portfolio. Although the solution in [19] uses the hierarchy of credential types for checking whether the disclosure of a subset of the portfolio components satisfies a given server request, it does not consider this hierarchy in the definition of privacy preferences. An interesting open issue consists in exploiting the hierarchy of credential types to make the definition of privacy preferences more user-friendly.
- *Proof of possession*. The values modeling privacy preferences are traditionally associated with credentials and/or attributes and express how much their owner values their release. Recent technologies, however, permit release of proofs of possession of credentials and proofs of satisfaction of conditions defined on attributes. The release of a proof is usually considered less sensitive than the release of the credential/attribute on which the proof is based. This different disclosure risk should therefore be adequately modeled.
- *Shared knowledge*. Attribute-based access control solutions traditionally assume that the hierarchy of credential types and attribute names represent a common knowledge for the server and the client. However, this assumption does not always hold in real-life scenarios, where there may be mismatches due also to the fact that servers refer to credential and attribute types while clients refer to their instances. Access control models should be extended to handle this problem.
- *Integration*. Both the solutions developed to support client privacy preferences and the solutions proposed to protect the confidentiality of server policies do not consider the privacy requirements of the counterpart. It is therefore important to study new models that consider both client and server privacy needs.

The approaches proposed in the literature for the support of client privacy preferences present advantages and disadvantages complementary to each other. For instance, the solution in [29] has the advantage of usability, while the approach in [19] supports sensitive associations and disclosure constraints. An interesting open issue is therefore the definition of a model that combines the advantages of all the proposed approaches.

9. SUMMARY

We have analyzed the privacy issues that may arise in open scenarios, where the client accessing a service and the server offering it may be unknown to each other and need to exchange information to build a trust relationship. We have illustrated both the problem of taking client privacy preferences into account in credential disclosure and the problem of maintaining the confidentiality of server access control policies. For each of these problems, we have described some recent approaches for their solution and illustrated some open issues that still need to be addressed.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The advancements in Information and Communications Technology (ICT) allow users to take more and more advantage of the availability of online services (and resources) that can be accessed anywhere anytime.
2. True or False? The information that a client can provide to a server to gain access to a service is organized in a *portfolio* including both *credentials* signed by third parties and certifying client properties, and *declarations* stating certified properties uttered by the client.
3. True or False? Attribute-based access control restricts access to server service depending on the attributes and credentials that the requesting client discloses to the server.
4. True or False? Since clients and servers operating in open environments are assumed to be unknown to each other, they interact with the aim of building a trust relationship that will permit the client to gain access to a service offered by the server.
5. True or False? Given the server request, the client needs to determine which credentials and/or attributes to disclose to satisfy it.

Multiple Choice

1. With __________, servers regulate access to their services based on the attributes and certificates presented by the requesting client?
   A. privacy-enhancing technology
   B. location technology
   C. attribute-based access control
   D. executable policies
   E. data controller
2. The goal of the client and the server engaging in a negotiation protocol is that of ________ the sensitivity cost of the credentials and policies exchanged during a successful negotiation strategy.
   A. policy enforcement
   B. location technology
   C. valid
   D. minimizing
   E. Web Technology
3. The solution proposed for the simplified scenario where policies are not associated with a sensitivity cost (they can be freely released) is based on the definition of a _______ modeling the policies regulating credential disclosure at both the client and server side.
   A. data minimization
   B. *XACML*
   C. policy graph
   D. contradictory
   E. security
4. The solution for the more complex scenario where both credentials and policies regulating their release are associated with a sensitivity cost is based on a ________that consists of two steps.
   A. privacy metrics
   B. greedy strategy
   C. redundant
   D. privacy preferences
   E. taps
5. Since the __________ might be considered sensitive, the server does not reveal the threshold associated with its services to the client.
   A. irrelevant
   B. anonymous communication
   C. datahandling policies
   D. disclose-to
   E. server policy

EXERCISE

Problem

If an organization uses a distributed access control system, does it have to give up other access control methods or security measures?

Hands-On Projects

Project

Who does an organization have to trust with regard to a distributed access control system?

Case Projects

Problem

Exactly how is a user authenticated?

Optional Team Case Project

Problem

Do all distributed access control system users have to have client certificates issued by the same certificate authority?

ACKNOWLEDGMENTS

We would like to thank Sabrina De Capitani di Vimercati for suggestions and comments on the chapter organization and presentation. This work was partially supported by the Italian Ministry of Research within the PRIN 2008 project "PEPPER" (2008SY2PH4).

1. INTRODUCTION

Environmental monitoring systems allow the study of physical phenomena and the design of prediction and reaction mechanisms to dangerous situations. In its general form, a monitoring system consists of a certain number of sensors designed to measure different physical quantities, one or more processing nodes, and a communication network. The sensors provide output analogical signals, which are conditioned and converted into the digital domain. The digital signals are then transmitted to the computing devices, which perform the aggregation of the obtained data to understand the measured phenomenon.

In our modern society, these systems are becoming increasingly important for keeping the state of the environment under control. In fact, they have a fundamental role in detecting new environmental issues and in providing evidence that can help prioritize environmental policies. Such systems are also useful to better understand the relationship between the environment, economical activities, and daily life and health of people. For instance, weather affects agricultural prosperity and forest well-being, while environmental pollution affects human health and reduces the quality of water, land, cultivation, and forest. There is then great interest in monitoring the environment to associate possible effects with observed phenomena and predict critical or dangerous situations. For instance, today we know that there is a direct link between exposure to PM10 and PM2,5 and different pathologies of vascular systems. Moreover, natural resource management and preservation can also greatly benefit from using monitoring systems to observe the status and its evolution so as to initiate conservation actions when needed. Similarly, natural disaster detection, observation, and, eventually, prediction can be based on monitoring the geographical areas of interest. Another sector in which these systems are becoming highly significant is the monitoring of critical infrastructure, in particular encompassing railways, highways, gas pipelines, and electric energy distribution networks.

In the last several years, the environmental monitoring systems have been subject to fundamental changes due to rapid advancements in technology as well as the development of a global information infrastructure such as the Internet that allows an easy and rapid diffusion of information worldwide. As an example, advances in spectral and spatial resolutions, new satellite technologies, and progress in communication technologies have improved the level of detail of satellite Earth observations, thus making available high-resolution spatial and spectral data. Although such technological developments have the positive effect of expanding the application fields where environmental data can be successfully used, there is also a negative effect related to increased misuse of

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00047-7

environmental data and systems. As a matter of fact, seemingly innocuous environmental information can lead to privacy concerns. For instance, ambient environmental monitoring data could be used to identify small geographic areas. Property owners identified in the vicinity of a hazardous waste site or other pollution sources could experience decreased property values or increased insurance costs.

In this chapter, we aim at providing a comprehensive analysis of the main security and privacy issues that can arise when collecting, processing, and sharing environmental data. The main contribution of this chapter is the analysis of these security and privacy issues, which involve both the infrastructure of the environmental monitoring systems and the data collected and disseminated, along with possible countermeasures for mitigating them. The remainder of the chapter is organized as follows. Section 2 discusses the different kinds of systems and architectures used for environmental monitoring. Section 3 resents what kinds of environmental data are typically collected and analyzed. Section 4 illustrates the main security and privacy issues related to the collection, processing, and sharing of environmental data. Section 5 discusses how such security and privacy risks can be counteracted by adopting suitable protection techniques. Finally, Section 6 concludes the chapter.

2. SYSTEM ARCHITECTURES

Environmental monitoring systems have evolved from a simple computer with sensors to composite structures that include specialized subcomponents addressing particular data collection issues. These systems are typically classified by considering the system architecture, the geographical extension of the monitored phenomenon, or the number of functions performed by the system.

Based on the system architecture, environmental monitoring systems can be classified as *centralized*, *distributed*, and *remote sensing systems* [1]. Centralized systems comprise a single processor or controller, a limited number of sensors, and a simple output presentation interface (a single value on a display). Data are collected by sensors and transmitted to the processing unit that performs data analysis and feature extraction required by the application, and stores all relevant information as specified by the application itself. They may have small dimensions and be easily transported. Examples of centralized environmental monitoring systems are radiation detectors, gas detectors, and laboratory equipment. Centralized systems also include monitoring systems based on a single observation point or systems that use robotic architectures to monitor hostile or remote environments [2].

Distributed systems are composed of a high number of sensing nodes and can exploit distributed computing and storing abilities. A sensing node contains a limited number of sensors, a processing unit, and a network communication channel. Sensing nodes collect data may perform some local processing, and route data and information toward some processing nodes in the distributed structure. Some nodes have interfaces to deliver the results of their elaborations and storage devices to save acquired sensor data and processed information. Sensing nodes are deployed in a fixed position or may be mobile on boards of robots to explore the environment [3]. Some intelligence may be distributed in sensing and processing nodes to provide local abilities for data processing to extract knowledge as near to the sensors as possible, reducing the transmitted data or taking earlier local actions [4]. Sensing nodes can have self-configuration capabilities to adapt their operation to the environment and allow for easier deployment, especially when the environmental conditions are harsh or humans cannot reach the monitored place. Mechanisms are also introduced for effecting automatic network configuration if nodes are added or removed [4], for determining if node measurements are not necessary and thus save energy, or for allowing the nodes to move when a more suitable position is found [5]. Self-calibration techniques are used to set the operating parameters [6]. The distributed structures may help in limiting costs and may impact the environment (small and inexpensive sensors, shorter and cheaper sensor connections, small low-cost processing units for real-time operation, and possibly wireless transmission for limited interconnection costs).

In the simplest network topology, a central node processes data (Figure 47.1); even though continuous data transmission from sensing nodes leads to higher energy consumption, adjacent nodes may measure redundant or highly correlated data, and scalability may be limited due to computational and bandwidth issues.

To overcome these problems, hierarchical sensor networks have been used. These networks are usually

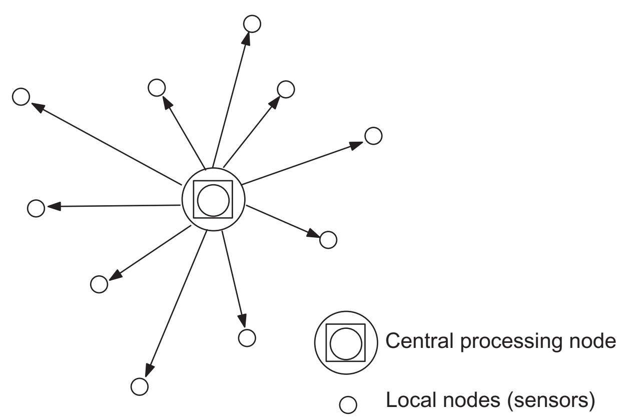

FIGURE 47.1 Sensor network with a central processing node.

composed of three-levels: *local nodes* (sensors), *intermediate nodes* (local aggregation centers, gateways, or base stations), and a *central processing* node. Some nodes may coordinate some sensors (cluster) by performing synchronization and data fusion [4] (Figure 47.2). Computation is distributed in the hierarchical structure to create abstract views of the environment at different abstraction levels and compact the information by extracting the relevant knowledge as locally as possible. Local processing should be performed carefully to avoid possible erroneous interpretation of the corresponding data at higher levels. Appropriate data aggregation techniques must be adopted to achieve a global understanding of the measured phenomena, while avoiding data loss and redundant transmissions [7].

Communications are a critical aspect of sensor networks. They can be wired as in the conventional architectures or wireless (wireless sensor networks [WSN]). Use of cables to power sensors and transmit the data can create difficulties. Low-power communication protocols and wireless interconnections are often used [8]. In these architectures, the geographical position of nodes may not be known a-priori: GPS or GIS systems are used to trace the positions of the data collected from sensors.

Sensing can be performed by using sensors for the specific quantities to be measured and placed locally at the point in which the measure has to be taken. In some environments, direct local sensing may be difficult or even impossible due to costs or environmental/operating conditions. To overcome this problem, for some quantities indirect measures can be taken by observing the point of interest from some distance. Visual sensor networks (VSNs) are an example of this approach: Their nodes are equipped with image-capturing devices and use image-based monitoring techniques. However, they require more complex devices, greater memory usage, higher bandwidth, and nodes with more power consumption. Hierarchical sensor network architectures, consisting of heterogeneous nodes, can be used to reduce the costs and computational load [9].

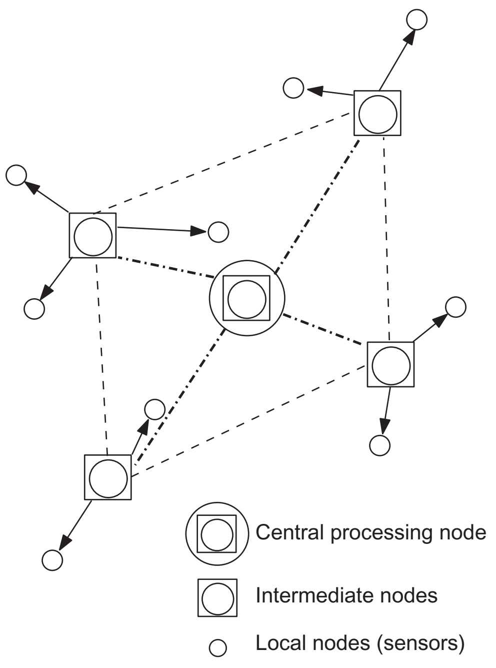

FIGURE 47.2 Hierarchical sensor network.

Remote sensing systems are based on signals and images acquired by sensors installed on artificial satellites or aircraft and are used for vast geographical phenomena. These systems can capture several types of quantities at a significant distance, for example, by aircraft or artificial satellites. Such systems can be passive or active. In the first case, the sensors only detect quantities naturally produced by the object (the radiations of the reflected sunlight emitted by the objects). Many passive sensors can be used according to the chosen wavelength and signal dimension (radiometers, multispectral, and hyperspectral imaging). Instead, active systems send a signal to the object to be monitored and measure the reflected pulse (RADAR, LIDAR, laser altimeters). Remote sensing techniques can be merged with terrestrial sensor networks to integrate local data with large-scale observations to enhance the observation quality [10].

Environmental monitoring systems can also be classified, according to their geographical extension, as *large-scale*, *regional*, or *localized* monitoring systems [11]. Large-scale environmental monitoring systems are deployed when there is the need to cover a vast geographical area, such as several countries, or even the whole earth globe. They are typically based on distributed networks or remote sensing, and they are used, for example, for monitoring seismic activity [12–14], geophysical monitoring [15], earth pollution [16,17], global water quality [18], wildfire [19], meteorological data [20–23], arctic ice and snow [20,24], desert sand storms [25], or their combinations (see checklist: An Agenda for Action for Privacy and Security of Environmental Compliance Monitoring Systems) [26–29].

Regional monitoring systems typically cover areas such as cities, forests, or region. They are used, for example, for monitoring water quality [30], air quality [31,32], meteorological information [33–36], regional oceanographic processes [33,36], or wildfires [37–41].

Localized systems are used for monitoring very localized points, for example, lakes, volcanoes, indoor environments, or buildings. Several practical cases are available, for example, for the quality of the water in lakes, rivers, or small bays [42–44], the state of glaciers [45], underwater currents [46], air quality in small environments [47–49], and urban pollution (noise [50],

An Agenda for Action for Privacy and Security of Environmental Compliance Monitoring Systems

The EPA's national compliance monitoring program is responsible for maximizing compliance with federal environmental statutes dealing with prevention and control of air pollution, water pollution, hazardous waste, toxic substances, and pesticides. Under these statutes, the EPA and its regulatory partners monitor activities under 44 separate statutory programs. The statutory and regulatory requirements of these programs apply to approximately 41 million regulated entities, such as sewage treatment plants, gas stations, and hospitals. The EPA regulates chemicals and monitors compliance with environmental laws and regulations designed to reduce pollution to protect public health and the environment. Without compliance with the environmental requirements, the promulgation of laws and regulations has little impact. Compliance monitoring consists of a variety of activities including (check all tasks completed):

_____**1.** Conduct of compliance inspections, civil investigations, and evaluations under the air program.
_____**2.** Determination of facility/site compliance status.
_____**3.** Entry of results of activities into national data systems.
_____**4.** Response to citizen complaints.
_____**5.** Participation in development of rules to ensure they are enforceable.
_____**6.** Development of compliance monitoring tools such as inspection checklists/guides.
_____**7.** Procurement and dissemination of new compliance monitoring technologies such as remote sensing and hand-held computers.
_____**8.** Development and delivery of training for compliance monitoring personnel.
_____**9.** Support in the development of enforcement cases.
_____**10.** Development of state, tribal, local, and international compliance monitoring capacity.
_____**11.** Funding and oversight of regional, state, and tribal compliance monitoring programs.

radiation [51]). Localized systems are also used for disaster prevention (for active volcanoes [52], landslides [53], and critical infrastructures [54,55]).

More complex measurement systems, called *heterogeneous sensor networks*[11], have been created by integrating combinations of subsystems of the above types, with different scales and functions, especially when applications use systems already deployed in the environment of interest or when quantities must be measured in a heterogeneous setting. Some examples of this kind of system are the UK Climate Change Network [21,23] for land and aquatic places in the UK, the Global Earth Observation System (GEOSS) [28] for different environmental processes all over the world, and the ORION project [56] for oceans. Heterogeneous systems may combine information from local sensor networks with satellite information, for example, linking local sensor networks on a planetary scale [10] or aggregating local imaging data with satellite imaging techniques [57].

Environmental monitoring systems are also characterized by the type of functionalities performed [11]. In *monofunction systems*, the measured quantities are directed to provide knowledge for a single application, as in monitoring volcanoes [52] or buildings [55]. In *multiple-function systems*, data are collected (possibly in subsets of different types from different locations) and used by different applications and even for different global purposes, thus integrating various monitoring systems into a single infrastructure ([58]. Multiple-function systems also support environmental monitoring, border control, and surveillance applications, while [26,27] dealing with climate and resource monitoring, topography, and disaster prevention).

3. ENVIRONMENTAL DATA

Before describing the security and privacy issues that characterize an environmental monitoring system, it is fundamental to clarify what kinds of environmental data can be typically collected and possibly released to the public. Different data types are used in environmental monitoring systems, depending on the context. The used sensors can, in fact, measure data related to different physical quantities: movement, speed, acceleration, force, pressure, humidity, radiation, luminosity, chemical concentration, audio, video, and so on. Usually, the acquired data consist in monodimensional or multidimensional signals (images/frame sequences). The data used by large-scale environmental monitoring systems are inherent to the physical quantities chosen to measure a single phenomenon, and the data are captured and aggregated at a high frequency to perform a continuous monitoring of the phenomenon.

In most cases, the geographical positions of the measuring nodes are fixed, known a priori, and released publicly. For instance, the system described in [34] was composed of 192 measurement stations with fixed and known positions, and performed a continuous monitoring of air temperature, humidity, precipitation, solar radiation, wind speed and direction, and atmospheric pressure. The system described in [12,14] was composed by more than 150 measurement stations with fixed and known positions, and measured data from seismographs. The system proposed in [16,17] used different UV radiation detectors to perform a continuous monitoring of radiation. In the case of regional or localized environmental monitoring

networks with multiple functions, nodes may not have fixed or known a-priori positions, are equipped with GPS devices, use wireless transmission techniques, and are powered using batteries. For this reason, the data transmission frequency is often smaller than the one used in large-scale environmental monitoring systems. For instance, the system described in [33,36] performed the continuous monitoring of the waves along the coasts of Louisiana and the Mexican gulf, measuring the wave height, their period, the direction of propagation, the water level, and the direction and speed of the currents. Different kinds of nodes with wireless transmission capabilities can be used. For instance, a volcano monitoring system is described in [52] and uses nodes with infrasound sensors and GPS devices. An experimental visual sensor network for fire monitoring is proposed in [37,40].

At a high level, the life cycle of environmental data can be divided in three macro-steps: *collection*, *storage*, and *publication*. Data are collected from the environment and stored at the sensor and/or processing nodes. The format of the stored data depends on the specific purpose for which such data have been collected. Authorized parties can access the environmental data for analysis or other purposes. The environmental data (or a subset of them) can then be made publicly or semipublicly available. The data are typically published in the form of *macrodata* (tables reporting aggregated information about an environmental phenomenon) or *microdata* (records reporting data related to specific physical measurements) [59].

In the remainder of this chapter, we illustrate some security and privacy risks that may arise in the data life cycle. To fix ideas and to clarify the following discussion, we refer our examples to a scenario characterized by a localized network in the city of San Francisco, which is under the control of the local municipality. The system is distributed and the sensor nodes are organized according to a centralized configuration. The collected data are stored at processing node PN. *Alice* is an adversary that tries to violate the monitoring system and to discover sensitive information. We also consider a fictitious factory A, which improperly releases pollutants and production rejects into the environment.

4. SECURITY AND PRIVACY ISSUES IN ENVIRONMENTAL MONITORING

Environmental monitoring systems and the data they collect can be vulnerable to security and privacy risks [60]. In particular, security risks are related to the threats that can undermine the *confidentiality*, *integrity*, and *availability* of both the data and the monitoring systems in their entirety (e.g., system architecture and communication infrastructure). Conversely, privacy risks are related to those threats that can allow an adversary to use the environmental data for *inferring sensitive information*, which is not intended for disclosure and should be kept private. Security and privacy risks are not independent: They are often correlated, and an adversary can exploit a security violation for breaching data privacy. As an example, suppose that *Alice* successfully violates the physical security of processing node PN, causing a security violation that can allow her to access private information related to the pollutant levels in the air of San Francisco. This security violation can allow *Alice* to infer pathologies of the citizens of a given area of the city, therefore violating their privacy.

In this section, we present and illustrate through examples the main security and privacy risks that can arise in the context of environmental monitoring. Note that, in the following discussion, we consider neither the classical security problems related to failures of systems and applications due to errors, nor the reliability and dependability aspects characterizing the system, as our goal is to focus on the less well-known security and privacy issues.

Security Risks

Broadly speaking, in our environmental monitoring scenario, security risks are related to all threats that can: (1) damage the infrastructure of the monitoring system; (2) violate communication channels connecting different components of the monitoring system; or (3) allow unauthorized parties to intrude into the monitoring system for malicious purposes. We now describe these threats in detail.

Damages to the System Infrastructure

Any attack performed with the aim of physically damaging the monitoring system can put at risk the confidentiality, integrity, and availability of the collected environmental data. For instance, suppose that the local municipality of San Francisco wants to build a new playground for children and, to determine the safest location, it analyzes the collected environmental data to discard polluted areas of the city. Suppose also that *Alice* maliciously damages the sensor nodes close to factory A, to hide evidence of the pollutants and production rejects release. Clearly, this compromises the collection of the environmental data, since these sensor nodes become unavailable (data availability violation). An analysis of the partial environmental data available to the local municipality can erroneously identify an area close to factory A as the safest area for building the new playground. If this were to happen, children would be exposed to pollutants and production rejects. The same risks apply when

all sensor nodes are working properly but the processing node gets attacked and becomes unavailable: In this case, the analysis of the environmental data would not be based on the latest measurements of the sensor nodes, and the results might be compromised. Note that these attacks can impact any of the three steps of the environmental data life cycle, as similar problems arise when an adversary succeeds in compromising the nodes collecting data (collection step), the database where environmental data are stored (storage step), or the systems where they are published (publication step).

Violation of the Communication Channels

All communication channels connecting the different components of a sensor network can represent a possible target for an adversary. In particular, the adversary might be a *passive adversary*; that is, she could be interested only in monitoring the communication channels to observe information that she would not be able to access, or an *active adversary*; that is, she could attempt to delete or modify data transmitted on such channels. These two scenarios configure two "classical" security attacks, which can intuitively violate the confidentiality and integrity of the data. Besides such attacks, an adversary can also be interested in monitoring the *accesses* performed on the data by the authorized parties, to discover some sensitive information about them. For instance, the fact that an authorized party accesses data related to the concentration of particulates reveals that the party is interested in discovering the polluted areas. If the party is a building constructor, this may imply that the party is interested in building a new apartment complex, and therefore the adversary can speculate on the costs of the lands. Effective protection of data access also requires the protection of *access patterns*: An adversary should not be able to see whether two accesses performed by two different parties aimed at the same data. For instance, *Alice* should not be able to see if two competitors are interested in performing similar analysis on the environmental data. If so, *Alice* would be able to sell this knowledge to one of the two competitors. Note how the latter two attack scenarios configure two examples of a security violation causing a privacy breach.

Unauthorized Access

Environmental data should be available only to users and parties authorized by the data owner. Clearly, restrictions on accesses to environmental data only apply when such data are not publicly released. Unauthorized accesses can possibly involve the database where environmental data are stored after their collection and analysis, or the sensor nodes. The storage server can be a local server, under the control of the data owner, or an external, third-party storage server. In the first case, the server can be considered trusted (data can be safely stored), and access control should only be enforced against users requesting access to the stored data. In the second case, the external storage server is not considered trusted, and therefore access restrictions should also take into account the fact that the server itself should not be able to access the stored data. An adversary intruding into sensor nodes can be interested in accessing raw data to update them, or to inject false data so that tampered data are sent to the processing node. For instance, *Alice* can be interested in manipulating the measurements performed by the sensor nodes close to factory A to reduce the concentration of a specific harmful substance. An adversary intruding into the storage servers is clearly interested in accessing environmental data after their collection, normalization, and analysis. Note that collected data can also be stored together with other datasets and, as a consequence, the adversary can discover correlations and dependencies among these different data sets. In all these cases, both data confidentiality and integrity are at risk.

Privacy Risks

Privacy risks are related to all threats that can allow an adversary to infer sensitive information from the collected environmental data. Such inferences can be *direct*, that is, caused by observations in the data collection (an adversary observing production rejects can discover confidential details of the productive processes of a company), or indirect (studies on the presence of polluting substances in geographical areas or workplaces can be correlated with studies on the relationship between correlating pollutants and diseases, revealing possible illnesses of individuals living in those areas). Inferred sensitive information can involve individuals, the environmental area on which data have been collected, and also areas close to or correlated with it. As an example, the knowledge that some geographical areas are polluted with harmful substances can also affect individuals who live in other areas if they own properties in the polluted areas. In fact, due to such knowledge, the value of their properties could decrease. Privacy risks can occur when environmental data are made publicly available (publication step) or when they are (properly or improperly) accessed; they can be a consequence of data correlations and associations, observations of data evolutions, unusual data, or knowledge of users' locations.

Data Correlation and Association

A possible means through which sensitive information can be inferred is represented by the natural correlations

existing among different phenomena. To illustrate, consider a life and sickness insurance company in San Francisco. Suppose that a third-party organization releases a study illustrating the relationship existing between pollutants and rare diseases. Suppose also that the insurance company accesses this study. By analyzing environmental data collected by the local municipality and comparing them with the study, the insurance company can decide to increase the risk associated with citizens living in polluted areas of San Francisco and recompute their insurance policies. In addition to correlation, also the association of environmental data with other information coming from different sources can be exploited for inferring sensitive information. For instance, suppose that *Alice* can access a collection of data recording the medical histories of a community of patients. *Alice* might then link such data with airborne pollution studies (by exploiting city and county zones that are used to identify population exposed to specific airborne pollutants) and thereby violate patients' privacy.

Data Evolutions

To obtain more meaningful data, sensor nodes can perform several measurements of quantities of interest over time. For instance, a measuring station can continuously record the noise level in a given area of a city. While a high number of samples allows for better analysis of a given phenomenon, such repeated measurements can open the door to possible inference channels leaking sensitive information. For instance, suppose that *Alice* wants to discover the timetable of the freight trains traversing the railroad in San Francisco, which is kept secret by the local train company. Suppose also that the environmental monitoring of the local municipality includes measurements of the noise pollution in the city. Having access to the measurements collected close to the railway, *Alice* can notice peaks in the noise levels and correlate this information with the public timetables of passenger trains, thus reconstructing the freight trains' timetable.

Unusual Data

Intuitively, if the measurements obtained from an environmental monitoring system deviate from what is expected or considered as usual, a high risk of sensitive information inference can arise. To illustrate, suppose that the results of the environmental monitoring of the San Francisco city area show a high level of radioactivity. If the neighbor cities do not show such a high level of radioactivity, then these values can be considered surprising, and may witness the existence of a neighbor location storing radioactive material (nuclear weapons, or rejects of nuclear power plants). Otherwise, if the same level of radioactivity is observed also in other cities, the radioactivity in San Francisco can be due to some peculiarities of the soil.

Users' Locations

Mobile phones and smartphones are portable computers that more and more users have and carry with them all times. In the near future, we can imagine that our phones will be equipped with sensors and applications specifically targeted to the environmental monitoring, leading to a *pervasive* environmental monitoring where the sensing will be directly performed by users who will collect data related to the locations they visit. Since users move around the space, measurements have to be tagged with the location in which they have been captured. An adversary able to track the movements of a given user can violate her privacy discovering her frequent addresses (home and workplace), usual movements (from home to work), and habits, and, accordingly, can infer sensitive information about her. For instance, suppose that *Alice* gains access to the set of location-tagged environmental measurements performed by her colleague *Bob* with his smartphone. *Alice* can notice that *Bob* visits a clinic for cardiovascular diseases every day, discovering that *Bob*, or one of his relatives or close friends, suffers form a heart problem.

5. COUNTERMEASURES

We now describe possible countermeasures that can be adopted to avoid or mitigate the security and privacy risks described in the previous section. In the remainder of this chapter, we will refer our examples to the environmental data in Table 47.1, reporting a possible example of a collection of noise and PM10 values measured in the San Francisco area. Each row reports the GPS coordinates of the node that performed the measurement, personal information (name, date of birth, and ZIP code) of the owner of the area in which the sensor node is placed, and the noise and PM10 values measured by the node, expressed in dB and $\mu g/m^3$, respectively.

Counteracting Security Risks

The security risks related to the system architecture can be prevented by hardening the physical security of the whole system architecture and by adopting intrusion detection systems [61]. Fault-tolerance solutions can also be helpful when an adversary turns out to be successful and some parts of the system report damages. For instance, a simple solution for ensuring the availability of the data stored in the processing node consists in replicating the data on several machines, possibly located in

TABLE 47.1 An Example of a Collection of Environmental Data.

different sites. The classical attacks on the communication channels can be prevented by encrypting the traffic, though lightweight solutions appear to be suitable for an environmental monitoring scenario, where data measurements are typically performed by sensor nodes with limited computational capabilities [62]. More challenging are the problems of ensuring appropriate protection against nonclassical attacks that analyze data access and access patterns, and of enforcing access restrictions under the assumption that the set of authorized users can dynamically change and might not be known a priori. In the remainder of this section, we illustrate possible strategies that can be adopted for addressing these two issues.

Protecting Environmental Data Access Patterns

The problem of protecting data access and access patterns from external observers and the storage server itself has been mainly studied in the database field [63]. A possible solution to the problem of ensuring that an adversary cannot infer any sensitive information from the observations of accesses to data is to change the physical location (blocks of the hard disk) where data are stored at each access. The technique in [63] goes in this direction, enabling authorized parties to access the stored data while guaranteeing: (1) *content* confidentiality (data privacy is maintained); (2) *access* confidentiality (the fact that an access aims at a specific data item is protected); and (3) *pattern* confidentiality (the fact that two different accesses aim at the same data items is protected) from any observer, including the storage server itself. The technique is originally proposed in scenarios of data outsourcing, but it nicely fits a scenario in which a collection of environmental data needs to be stored and maintained private, and each access to certain information is performed by a request issued by a *trusted client*, directly interacting with the storage server.

Adopting this proposal, content, access, and pattern confidentiality are guaranteed by organizing data in an ad-hoc data structure, called a *shuffle index*. Such a shuffle index assumes data to be organized in an unchained B + −tree, and encrypts data at the node level, so that real (plaintext) values are protected from the (possibly untrusted) storage server. In the B + −tree, data are indexed over a candidate key defined for the data collection, and actual data items are stored in the leaves of the tree according to their index values. Accesses to the data items stored in the tree are based on the value of the associated indexes. Note that, to avoid improper leakage of information to the storage server, the B + −tree does not include any link from a leaf to the next one. The rationale behind this is that such links would expose the order relationship among index values in different nodes.

Data encryption ensures content confidentiality, while access and pattern confidentiality are safeguarded by the client by means of: (1) hiding the real (target) request within cover (fake) requests; (2) caching target searches recently performed by users; and (3) shuffling, at each request, the content among blocks stored at the server. These three strategies work as follows:

- Cover searches hide a request in a set of fake ones, thus introducing confusion on the requested target. Cover searches are executed in parallel to the target search, and the number of cover searches can be customized to tune the offered protection level.
- Cache avoids the client to search in the B + −tree for the same target in two close queries. The client maintains a local copy of the nodes forming a path in the

B + −tree reaching a target value. The size of the cache determines the number of last target searches that are maintained in the cache itself.

- Shuffling implies modifying the data structure at every access and shuffling content among its blocks. The shuffling operation destroys the one-to-one correspondence otherwise existing between a block and the node of the B + −tree stored in it. In this way, repeated accesses to the same node might actually refer to searches for different data items, while different accesses to different nodes might refer to searches for the same data item.

Enforcing Access Restrictions on Environmental Data

To prevent unauthorized access to the system, an access control mechanism is needed. A peculiarity of the environmental monitoring scenario is that the set of users authorized to access collected environmental data is typically very dynamic and may not be known a priori. For instance, consider the monitoring of air pollutants in the area of San Francisco. The collected and analyzed data could be accessed for analysis by the local municipality, but also by young researchers of local universities, which may have collaborations with other universities and therefore be part of a dynamic research group. According to this observation, the identity of the users accessing the data may not always be known in advance, and traditional identity-based access control techniques [64] might not be applicable. To overcome this problem, attribute-based access control might represent a viable solution [65]. In this case, rather than considering users' identities, the authorizations stating who can access what data are defined by taking into consideration properties (age, nationality, occupation) of the authorized parties. For instance, suppose that the local municipality of San Francisco aims at giving access to the collected environmental data only to U.S. citizens. To this aim, the access control policy might grant access to users showing that they hold a U.S. passport, regardless of their identity. Attribute-based access control has been introduced as a means of enforcing this kind of access restrictions in open environments. It is based on the assumption that typically each interacting party (e.g., a client and a server) has a portfolio of *credentials* and *declarations*, either issued and certified by trusted authorities or self-declared by the party herself [65]. More precisely, a credential includes a list (possibly empty) of certified attributes of the form ⟨`attribute name`, `attribute value`⟩ representing the subject's attributes (e.g., name and surname contained in an electronic passport), the issuer's public key, the subject's public key, a validity period, and a digital signature. Declarations are pairs of the form ⟨`attribute name`, `attribute value`⟩ specifying the party's attributes (the professional status communicated by a user during a registration process) and are produced by the party itself, without any certification from a legal authority. A common assumption underlying attribute-based access control systems is that the set of credentials and declarations that can be released by a party is stored in a profile associated with the party itself.

Attribute-based authorizations involve a *subject*, an *object*, and a set of *actions* to which the authorization refers. A *subject* can be defined as a Boolean formula over declarations and/or credentials. Analogously, an *object* can be defined as a Boolean formula of *predicates* specifying given conditions on the metadata associated with objects. An authorization therefore states that all subjects with a profile that satisfies the conditions in the *subject* field can perform *actions* on the objects whose metadata satisfy the conditions in the *object* field [65]. An authorization might also contain other elements imposing further conditions on the authorization, such as the purpose of access or generic conditions that must be satisfied by the access request. For instance, consider the environmental data in Table 47.1. To read (action) a specific set of PM10 measurements in the San Francisco area (object) collected from a certain set of ZIP codes (condition to be satisfied by the object profile), an authorization can require the proof of majority age and a U.S. nationality (conditions to be satisfied by the subject's profile).

When an access request is submitted to the storage server (service provider), it is evaluated with respect to the authorizations applicable to it. An access request is allowed if the conditions for the required access are satisfied; it is denied if none of the specified conditions that might grant the requested access can be fulfilled. However, it may happen that the currently available information is insufficient to determine whether the access request should be granted or denied: In such cases, additional information is needed, and the requester receives an undefined response with a list of requests that she must fulfill to gain the access.

Counteracting Privacy Risks

To protect environmental data from inferences, it is necessary to adopt techniques limiting the analysis that an adversary can perform on them, and obfuscating correlations, associations, and dependencies among them. As previously mentioned, these kinds of inferences can arise whenever environmental data are properly or improperly accessed (when they are stored or outsourced), or when they are made publicly available. In the first case, the privacy of environmental data can be protected by adopting privacy-enhancing solutions devised for data storage and outsourcing (e.g., encryption and fragmentation). In the

latter case, solutions investigated in the context of privacy-preserving data publishing can be adopted. In the remainder of this section, we discuss some of these possible solutions and briefly overview how location privacy can be ensured in the context of environmental monitoring.

Encrypting Stored and Outsourced Environmental Data

Properly storing and maintaining a collection of environmental data that can include, for example, raw data, analysis results, and evidence of correlations among environmental factors is not a trivial problem due to the possible inferences that can arise when accessing such data. Ensuring an appropriate degree of data privacy is of paramount importance, especially when the storage server is not trusted for accessing the data. Clearly, storing environmental data in *encrypted form* can represent an intuitive solution to guarantee protection against inferences. In fact, an encrypted data collection will be accessible for analysis only to authorized users—that is, those who are provided by the data owner with a decryption key.

Ensuring proper access to encrypted data is, however, a challenging problem, since different users are typically authorized to access different portions of the stored data. To ensure that all authorized parties can access *all and only* the data for which they have the appropriate authorization, data encryption can be combined with access control, leading to a peculiar kind of encryption usually referred to as *selective encryption* [66,67]. By adopting selective encryption, the keys with which data items are encrypted are regulated by the authorizations holding on the data, and different data items are encrypted with different keys, mapping an *authorization policy* into an equivalent *encryption policy*. As a consequence, an authorization to access a data item translates into knowledge of the key with which the data item is encrypted (for efficiency reasons, selective encryption is typically assumed to use symmetric encryption). An intuitive solution for enforcing selective encryption consists in encrypting each data item with a different key and providing each user with a set of keys, including all those used to encrypt the data items she can access. Such a naïve solution is, however, not viable in practice due to the unacceptable key management burden left to users: Each user would be required to manage as many keys as the number of data items she is authorized to access. This issue can be conveniently overcome by adopting *key derivation* methods. Basically, a key derivation method allows the computation of an encryption key starting from another key and some public information [66]. Adopting a key derivation technique, each user in the system is provided with a unique key. The set of keys in the system is then built in such a way that, starting from her own key and according to a *key derivation structure*, each user can compute all and only the keys needed for decrypting the resources she can access.

Among the possible key derivation strategies, *token-based* key derivation [66] results are particularly appealing for storing or outsourcing (environmental) data. In fact, this solution minimizes the amount of re-encrypting and re-keying required to enforce changes and updates to the authorization policy. Broadly speaking, token-based key derivation works as follows. Given a key k_i in the set of keys of the system, identified by public label l_i, a different key k_j can be derived from k_i and l_j through a so-called *token* $d_{i,j}$, computed as $k_j \oplus h(k_i,l_j)$, where $\oplus$ is the bitwise xor operator and h is a cryptographic function (e.g., a secure hash function). Note that the key derivation can be iteratively applied via a chain of tokens, and, since tokens are public pieces of information, all tokens defined in the system are stored in a public catalog. For instance, given three different keys k_i, k_j, and k_h, and two tokens $d_{i,j}$ and $d_{j,h}$, a user who knows (or can derive) key k_i can first use $d_{i,j}$ to derive k_j and, from k_j and $d_{j,h}$, she can then derive k_h. The effect of providing a user with a set $K = \{k_1, \ldots, k_n\}$ of keys is therefore conveniently obtained by providing the user with a single key $k_i \in K$ and publishing a set of tokens allowing the (direct or indirect) derivation of all keys $k_j \in K$, $i \neq j$. In this way, the user can derive all the n encryption keys, while having to worry about a single one.

To implement updates in the authorization policy regulating access to the stored data (insertion/deletion of a user or data item and grant/revoke of a permission), a subset of the keys and of the tokens defined in the system must be updated, and some data items must accordingly be re-encrypted. To limit computational burden, the solution in [66] proposes a two-layer encryption strategy called *over-encryption*. By adopting over-encryption, policy updates can be performed on encrypted resources themselves, without the need of decrypting them: In this way, the storage server itself can directly manage policy updates.

Fragmenting Stored or Outsourced Environmental Data

When encryption results are too heavy or when encrypting the whole data is an overdue, alternative solutions can be adopted. In fact, if what is sensitive is the data association instead of specific data values, solutions based on the vertical fragmentation of the data can be adopted. The intuition is very simple: When the joint visibility of some pieces of information is sensitive, such pieces of information are split in different portions that are not joinable. Fragmentation can be adopted by itself or coupled with

encryption. For instance, suppose that the collected environmental data include information about the concentration of a pollutant in an area, the area, and the owner of the properties within the area. Suppose also that the data holder wants to protect the identities of the owners of polluted properties. Such a collection of environmental data can be easily split in two fragments: One fragment includes the concentration of the pollutant and the corresponding area (with the information about the properties' s owner possibly encrypted), and the other fragment includes the information about the owners.

Data fragmentation has been deeply studied in the context of data outsourcing and publication in order to vertically fragment the set of attributes composing the schema of a relation to be outsourced or published in such a way to satisfy all confidentiality constraints defined by the data holder. Confidentiality constraints are subsets of attributes composing the original schema. Depending on the number of attributes involved, confidentiality constraints can be classified as: (1) *singleton constraints*, stating that the values of the attribute involved in the constraint are sensitive and cannot be released (the SSNs of patients hospitalized for a given respiratory disease due to PM10 exposure are sensitive per se and should be kept private); and (2) *association constraints*, stating that the association among the values of the attributes in the constraint is sensitive and cannot be released (the association between the name and the respiratory illness of a patient can be considered sensitive and should be protected from disclosure). Several fragmentation techniques have been proposed in the literature, and these techniques can be classified based on how they fragment the original relation schema and whether they adopt encryption.

The first strategy [68] couples fragmentation with encryption and is based on the assumption that fragments can be stored on two noncommunicating servers. When some confidentiality constraints cannot be solved by fragmentation, at least one attribute appearing in such constraints is encrypted. This technique strictly relies on the absence of communications between the servers storing the fragments. However, since collusions among servers can restore the original relation schema compromising the protection of sensitive data, alternative techniques have been proposed for enforcing confidentiality constraints.

The technique in [69] enforces confidentiality constraints coupling fragmentation with encryption, while removing the assumption of absence of communication among the storage servers. This technique satisfies singleton constraints by encrypting the values of the involved attributes. Association constraints are satisfied by adopting either fragmentation (storing the involved attributes in different fragments) or encryption (encrypting at least one of the involved attributes). However, this technique favors fragmentation over encryption: If a confidentiality constraint can be satisfied via encryption or fragmentation, such a constraint will be enforced with fragmentation. To ensure that no sensitive association can be reconstructed, each attribute must appear in the clear in at most one fragment. This makes the different fragments not joinable, and, therefore, all fragments might also be stored on a single storage server. Also, to guarantee the possibility for authorized users to run queries against the data collection, at the physical level each fragment stores all attributes of the original relation schema, either in the clear or encrypted, so that no confidentiality constraint is violated. For instance, consider the environmental data reported in Table 47.1, and suppose that there are seven confidentiality constraints (c_0,. . .,c_6) as reported in Figure 47.3.

Intuitively, these confidentiality constraints state that: (1) the list of the sensor GPS positions is considered sensitive (c_0); (2) the association of the landowners' names with any other information in the relation is considered sensitive (c_1,. . .,c_4); and (3) attributes DoB and ZIP can be exploited to infer the identity of the landowners and, therefore, their associations with the collected noise and PM10 values are considered sensitive (c_5 and c_6). Table 47.2 represents a possible fragmentation of Table 47.1 satisfying all the defined confidentiality constraints.

Attribute `Enc_T` contains the encrypted version of all attributes appearing in the original relation but not in the clear in the fragment. Note that attribute `SensorPosition` is the only attribute not appearing in the clear in any fragment since it is the only attribute involved in a singleton. Therefore, attribute `Enc_T` of the first fragment on the left-hand side in Table 47.2 includes in encrypted form the set {`SensorPosition, DoB, ZIP, PM10, Noise`} of attributes. Similarly, attribute `Enc_T` of the second and third fragment in Table 47.2 includes the sets {`SensorPosition, Name` } and {`SensorPosition, Name, DoB, ZIP`} of attributes, respectively.

Favoring fragmentation over encryption, the technique in [69] aims at limiting the overhead conveyed by encryption. There are, however, situations calling for a complete departure from encryption. The technique in [70] avoids the use of encryption and relies solely on fragmentation for satisfying confidentiality constraints. The assumption is that the data owner is willing to store a limited portion

- c_0 = {`SensorPosition`}
- c_1 = {`Name, DoB`}
- c_2 = {`Name, ZIP`}
- c_3 = {`Name, PM10`}
- c_4 = {`Name, Noise`}
- c_5 = {`DoB, ZIP, PM10`}
- c_6 = {`DoB, ZIP, Noise`}

of the data, whenever needed for enforcing confidentiality constraints. In this context, confidentiality constraints are satisfied by storing (at least) one attribute for each constraint at the data owner side. This fragmentation technique builds a pair of fragments, one stored on the data owner and the other one at the external storage server. Assuming that the storage capacity of the data owner is limited, each attribute of the original schema should appear in only one fragment in order to avoid replication of attributes that are already stored at the server side. To illustrate, consider the environmental data set in Table 47.1 and the set of confidentiality constraints in Figure 47.3, in which there is a possible fragmentation where attributes `SensorPosition`, `Name` and `ZIP` are stored at the data owner side, while attributes `DoB`, `PM10` and `Noise` are stored externally. Note that, unlike the fragmentation in Table 47.2, no attribute is encrypted (all attributes belonging to the original schema appear in the clear in exactly one fragment).

By adopting this technique, we see that the execution of queries involving attributes stored in the two fragments requires that the two fragments must have a common key attribute, so as to guarantee a lossless join property (attribute `T_Id` in the fragments in Table 47.3). To increase the utility of fragmented data, the fragmentation process can also take into consideration *visibility constraints*, expressing views of data that the fragmentation should satisfy. Visibility constraints permit the expression of different needs of visibility, such as visibility over the *values* of a single attribute, visibility over the *association* among the values of the attributes, or *alternative* visibility over different attributes [71]. Furthermore, fragments can be complemented with a sanitized release of the sensitive associations broken by fragmentation. Such a release takes the form of *loose associations*, defined in a way to guarantee a specified degree of privacy. A loose association reveals some information on the association broken by fragmentation by hiding tuples participating in the

associations in groups, and providing information on the associations only at the group level (in contrast to the tuple level) [71,72].

Protecting Published Environmental Data

When environmental data are publicly released, the possible countermeasures for their protection depend on the format of the data themselves (see Section 3). In the following, we illustrate how it is possible to publish environmental data while ensuring appropriate privacy protection, in the cases of both macrodata and microdata.

Publishing Environmental Macrodata

If environmental data are published through macrodata tables, they are released as aggregate values and do not contain information specifically related to single individuals or single environmental measurements. However, sensitive information can still be leaked. For instance, consider a macrodata table reporting the concentration of a pollutant during the day and night for each county of a given region. The cells of the macrodata table that contain a high value can be considered sensitive since they indicate that the persons living in the high-polluted counties may have a high probability of suffering from specific illnesses. The content of these cells therefore needs to be somehow protected.

A macrodata table can be protected before or after tabulation. In the first case, the objective is to apply some protection techniques to the collected data (data swapping, sampling, noise addition), so that the computed aggregate values can be considered safe. In the latter case, the protection techniques typically operate in two steps since they first discover sensitive cells, that is, cells that can be easily associated with a specific respondent, and then protect them [59]. We now describe how sensitive cells can be discovered and protected.

Detecting Sensitive Cells Sensitive cells can be identified according to different strategies [72]. An intuitive strategy is the so-called *threshold rule*, according to which a cell is sensitive if the number of respondents who contribute to the value stored in the cell is less than a given threshold. The *(n,k)-rule* states that a cell is sensitive if less than n respondents contribute to more than k% of the total cell value. Other examples of techniques are the *p-percent rule* and the *pq-rule*. According to the *p-percent rule*, a cell is sensitive if the total value of the cell minus the largest reported value v_1 minus the second largest reported value v_2 is less than $(p/100) \cdot v_1$ (the reported value of some respondents can be estimated too accurately). The *pq-rule* is similar to the *p-percent rule* but takes into consideration the value q representing how accurately a respondent can estimate another respondent's sensitive value ($p < q < 100$).

Protecting Sensitive Cells Once detected, sensitive cells can be protected by applying several techniques: *Cell suppression*, *rounding*, *roll-up categories*, *sampling*, *controlled tabular adjustment (CTA) function*, and *confidential edit* are possible examples of protection techniques. In particular, cell suppression consists in protecting a cell by removing its value (*primary suppression*). However, if some partial (marginal) totals of the table are revealed or publicly known, it might still be possible to re-determine the value of a suppressed cell or restrict the uncertainty about it. To counteract this risk, additional cells can be suppressed (*secondary suppression*). The rounding technique modifies the original value of a sensitive cell by rounding it up or down to a near multiple of a chosen base number. The roll-up categories technique modifies the original macrodata table so that a less detailed (of smaller size) table is released. Sampling implies that, rather than through a census, the macrodata table is obtained through a sample survey. The CTA technique consists in replacing the value of a sensitive cell with a different value that is not considered sensitive with respect to the rule chosen to detect sensitive cells. In a subsequent step, linear programming techniques are used to selectively adjust the values of the nonsensitive cells. The rationale behind confidential edit is to compute the macrodata table on a data set that is being slightly modified with respect to the original collection. In particular, a sample of the original records is selected and matched (i.e., a set of records with the same values on a specific set of attributes) in other geographical regions, and the attributes of the matching records are then swapped.

Publishing Environmental Microdata

Microdata tables contain specific information related to single entities (called respondents). To illustrate, consider the environmental data reported in Table 47.1, and suppose that the local municipality of San Francisco decides to publicly release the PM10 values in the area. Table 47.4 illustrates a microdata table that the municipality can prepare from the collected data and can then publicly release. Intuitively, the publication of a microdata table increases the privacy risks, and extreme attention has to be devoted to ensuring that no sensitive information is improperly leaked due to the release of such a table. In particular, in our example, the municipality must protect the fact that a given individual lives in an area with a high concentration of PM10 since an adversary may infer that the individuals living in such areas have a high probability of suffering from respiratory diseases.

Before publishing an environmental microdata table, all explicit identifiers have to be removed (or encrypted). For instance, Table 47.5 is a de-identified version of Table 47.4. In Table 47.5, the name of the landowners and the GPS position of the sensing devices (which would univocally identify the associated owner) have been removed by replacing them with value ***.

A de-identified table does not provide any guarantee of anonymity: In fact, besides identifiers, other attributes such as race, ZIP code, or gender (usually referred to as *quasi-identifiers*) can exist that might be linked to publicly available information to re-identify respondents. For instance, consider the public voter list reported in Table 47.1 and the de-identified microdata in Table 47.5 where there is only one landowner born on 21/06/1980 and living in the 94210 area. If this combination is unique in the external world as well, it identifies the first tuple of the microdata in Table 47.5 as pertaining to Adam Doe, 1201 Main Street, San Francisco 94210, thus revealing that Adam is the owner of an area where the level of PM10 is 60 $\mu g/m^3$.

Effective protection of data privacy can be achieved by adopting techniques that, for example, generalize the data while preserving data truthfulness: *k*-anonymity is the pioneering technique in this direction [73]. *k*-Anonymity enforces the well-known protection requirement, typically applied by statistical agencies, demanding that any released information should be indistinguishably related to no less than a certain number of respondents. This general requirement is reformulated in the context of *k*-anonymity as follows: *Each release of data must be such that every combination of values of quasi-identifiers can be indistinctly matched to at least k respondents*. Since, typically, each respondent is assumed to be represented by at most one tuple in the released table and vice-versa (each tuple includes information related to one respondent only), a microdata table satisfies the *k*-anonymity requirement if and only if: (1) each tuple in the released table cannot be related to less than *k* individuals in the population; and (2) each individual in the population cannot be related to less than *k* tuples in the table. Taking a safe approach, a microdata table is said to be *k*-anonymous if each combination of values of the quasi-identifier in the table appears with at least *k* occurrences. In this way, each respondent cannot be associated with less than *k* tuples in the table, and each tuple cannot be related to less than *k* respondents in the population, guaranteeing the satisfaction of the *k*-anonymity requirement.

To guarantee data truthfulness, *k*-anonymity is typically achieved by applying *generalization* and *suppression* over quasi-identifying attributes. Generalization substitutes the original values with more general values. For instance, the date of birth can be generalized by removing the day, or the day and the month of birth. Suppression consists in removing information from the microdata table. As an example, suppose that the quasi-identifier for Table 47.5 is composed by attributes `DoB` and `ZIP`. Table 47.7 represents a possible 2-anonymous version of the environmental data in Table 47.5. The 2-anonymous version has been produced by generalizing the date of birth of the landowners (releasing only the month and year) and the ZIP code (releasing only the first three digits of the code). It is easy to see that comparing the 2-anonymous table with the voter list in Table 47.6 and adversary cannot determine which one between the first two tuples is related to Adam Doe, since both of them share the same combination of attributes `DoB` and

`ZIP`. More precisely, each combination of values for attributes `DoB` and `ZIP` appear in the table with (at least) two different.

The k-Anonymity has been designed for counteracting *identity disclosure*; that is, it represents an effective solution for protecting the identities of the respondents of a microdata table. The original definition of k-anonymity has been extended to counteract the risk that sensitive information is leaked when releasing a microdata table (*attribute disclosure*). As an example, ℓ-diversity [74] and t-closeness [75] are two well-known extensions of k-anonymity, which slightly modify the k-anonymity requirement to ensure that neither identities nor sensitive information related to a respondent can be leaked when releasing a microdata table. The basic idea behind these approaches is to extend the k-anonymity requirement considering not only quasi-identifiers, but also sensitive attribute values when computing a privacy-preserving microdata table. To illustrate, consider the 2-anonymous microdata in Table 47.7. Although an adversary cannot precisely identify the tuple of Adam Doe between the first two in the table, they both share the same value for the PM10 measurement. As a consequence, the adversary is still able to discover that Adam Doe is the owner of a high polluted area. Table 47.8 illustrates a 3-diverse version of the microdata in Table 47.5, obtained by generalizing the date of birth to the year of birth, and the ZIP code by releasing only the first two digits. In this case, the tuple of Adam Doe can be one of the first four tuples of the table, but since these tuples assume three (hence the 3-diversity) different values for the PM10 concentration, the adversary cannot determine which is the concentration associated with Adam Doe's area.

The k-Anonymity, ℓ-diversity, and t-closeness have recently been modified and/or extended to suit particular releasing scenarios, characterized by particular assumptions, constraints, and privacy requirements, such as multiple table releases [76,77], data republication [78], nonpredefined or dynamic quasi-identifiers [79], customizable privacy protection [80].

Protecting the Privacy of Location Information in Environmental Data

The problem of protecting users' positions and movements has recently gained an increasing interest due to the proliferation of both mobile devices equipped with location capabilities and location-based services [81]. This has lad to the definition of different techniques for protecting location information, which can be nicely adapted to the scenario of pervasive environmental monitoring. In the remainder of this section, we survey three different classes of works that can be adopted in this scenario for protecting users' privacy.

The first class of works aims at protecting the privacy of anonymous users communicating with a location-based service provider whenever their real identities are not relevant for the service provision [81]. The goal of these

techniques is to avoid the possibility to *re-identify* users observing their position. Since in traditional location-based services users communicate with the service provider posing queries associated with their position, the intuition is that of ensuring that a same location be shared by at least a certain number of different users. These techniques guarantee indistinguishability of users by typically enforcing the requirement of *k*-anonymity [72], specifically tailored to fit the location-based scenario. In our environmental context, instead of issuing queries to a service provider, users communicate some environmental measurements: This translates to the requirement that a same sensed location should be shared by at least a certain number of different sensing users.

The second class of works aims at obfuscating the real position of the users in scenarios in which users are not anonymized and must provide their real identity to the service provider. The idea is that of *degrading the accuracy* of the location measurement. An intuitive strategy might consist in hiding the real position of a user with a set of other *n* fake positions, characterized by the same probability [82]. A different strategy is based on the adoption of some *obfuscation operators*, with the goal of balancing the accuracy of the position and the privacy requirements of the users. For instance, the technique in [83] quantifies privacy with respect to the accuracy of the location measurement, since the more accurate the measurement, the less the privacy. The defined obfuscation operators change the radius, or the center, of the original location measurement and are used to degrade the accuracy of the location measurement in such a way that, for each user, her privacy preferences are satisfied.

The third class of works focuses on *path privacy*, and aims at releasing a path shared by multiple users so to make them indistinguishable [84]. For instance, these solutions are based on a dynamic grouping of users [85], and protect path privacy enforcing a modified version of *k*-anonymity that requires that all *k* users associated with a specific location remain grouped together as time passes. A different solution is instead based on the release of fake (simulated) locations [86]. This technique adopts probabilistic models of driving behaviors, applied for creating realistic driving trips, and GPS noise to decrease the precision of the starting point of a trip, and is therefore more suitable for scenarios in which environmental sensing devices are placed on vehicles.

6. SUMMARY

In this chapter, we provided an overview of the systems and architectures used for environmental monitoring. We also presented an overview of the main security and privacy issues in environmental monitoring systems and discussed possible countermeasures for mitigating such issues. Our work can help in better understanding the security and privacy issues that characterized the environmental monitoring systems, and in designing novel environmental systems and applications that guarantee a privacy-aware collection, management, and dissemination of environmental data.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Environmental monitoring systems allow the study of physical phenomena and the design of prediction and reaction mechanisms to dangerous situations.
2. True or False? Environmental monitoring systems have evolved from a simple computer with sensors to composite structures that include specialized components addressing particular data collection issues.
3. True or False? Before describing the security and privacy issues that characterize an environmental monitoring system, it is fundamental to clarify what kinds of environmental data can be typically collected and possibly released to the public.
4. True or False? Environmental monitoring systems and the data they collect cannot be vulnerable to security and privacy risks.
5. True or False? Any attack performed with the aim of physically damaging the monitoring system can put at risk the confidentiality, integrity, and availability of the collected environmental data.

Multiple Choice

1. All _____________ connecting the different components of a sensor network can represent a possible target for an adversary.
   A. privacy-enhancing technology
   B. location technology
   C. communication channels
   D. executable policies
   E. data controller
2. What should be available only to users and parties authorized by the data owner.
   A. Policy enforcement
   B. Location technology
   C. Valid
   D. Environmental data
   E. Web technology

3. Which of the following are related to all threats that can allow an adversary to infer sensitive information from the collected environmental data?
   A. Data minimization
   B. XACML
   C. Privacy risks
   D. Contradictory
   E. Security
4. A possible means through which __________ can be inferred is represented by the natural correlations existing among different phenomena.
   A. privacy metrics
   B. greedy strategy
   C. sensitive information
   D. privacy preferences
   E. taps
5. To obtain more meaningful data, ________ can perform several measurements of quantities of interest over time.
   A. irrelevant
   B. sensor nodes
   C. data-handling policies
   D. disclose-to
   E. server policy

EXERCISE

Problem

What is the difference between the data gathered by the stationary and deployable monitors?

Hands-On Projects

Project

What are EPA's radiation air monitoring capabilities?

Case Projects

Problem

Are near-real-time radiation air monitors able to cover the whole United States?

Optional Team Case Project

Problem

What are deployable monitors? What do they measure?

ACKNOWLEDGMENTS

This work was supported in part by the Italian Ministry of Research within the PRIN 2008 project "PEPPER" (2008SY2PH4), and by the Università degli Studi di Milano within the "UNIMI per il Futuro −5 per Mille" project "PREVIOUS."

Virtual Private Networks

James T. Harmening
Computer Bits, Inc.

With the incredible advance of the Internet, it has become more and more popular to set up virtual private networks (VPNs) within organizations. Two types of VPNs are typically employed. The first will connect two separate local area networks (LANs), in different locations, to each other; while the second is a single remote computer connecting through the Internet, back to the home network. VPNs have been around for many years and have branched out into more and more varieties. (See Figure 48.1 for a high-level view of a VPN.) Once only the largest of organizations would utilize VPN technology to connect multiple networks over the Internet "public networks," but now VPNs are being used by many small businesses as a way to allow remote users access to their business networks from home or while traveling.

Consultants have changed their recommendations from dial-in systems and leased lines to VPNs for several reasons. Security concerns were once insurmountable, forcing the consultants to set up direct dial-in lines. Not that the public telephone system was much more secure, but it gave the feeling of security and with the right setup, dial-in systems approach secure settings. Sometimes they utilized automatic callback options and had their own encryption. Now, with advanced security, including random-number generator logins, a network administrator is far more likely to allow access to his network via a VPN. High-speed Internet access is now the rule instead of the exception. Costs have plummeted for the hardware and software to make the VPN connection as well. The proliferation of vendors, standardization of Internet Protocol (IP) networks, and ease of setup all played a role in the increasingly wide use and acceptance of VPN.

The key to this technology is the ability to route communications over a public network to allow access to office servers, printers, or data warehouses in an inexpensive manner. As high-speed Internet has grown and become prevalent throughout the world, VPNs over the public Internet have become common. Even inexpensive hotels are offering free Internet access to their customers. This is usually done through Wi-Fi connections, thus causing some concern for privacy, but the connections are out there. Moreover, the iPhone, Android, Windows, Blackberry, and other multifunction Web-enabled phones are giving mobile users access to the Internet via their phones. Finally, some of the best ways to access the Internet is via a wireless USB or PCMCIA card or wireless Hotspot from the major phone companies. These dedicated modem cards allow users to surf the Internet as

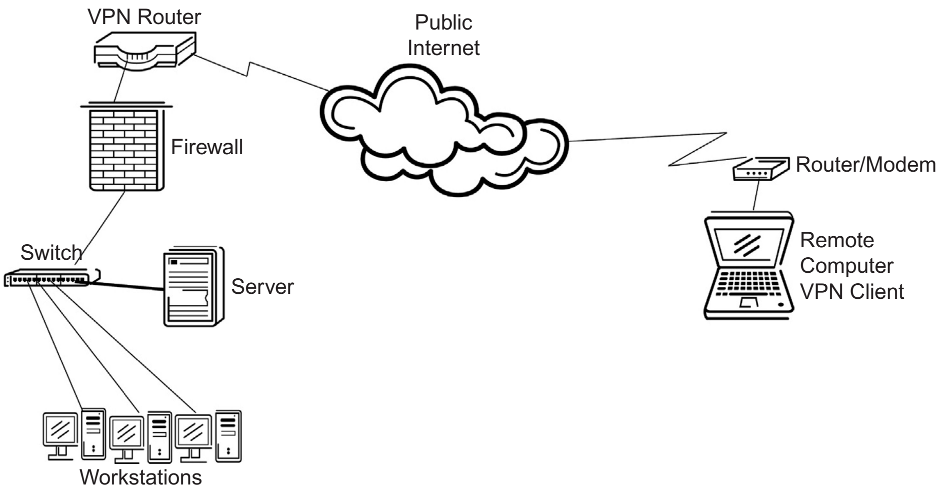

FIGURE 48.1 A high-level view of a VPN.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00048-9

long as they are in contact with the cell towers of their subscribing company.

One of the sources of our information on the overview of VPNs is James Yonan's talk at Linux Fest Northwest in 2004. You can read the entire presentation online at openvpn.net.

"Fundamentally, a VPN is a set of tools which allow networks at different locations to be securely connected, using a public network as the transport layer."[1] This quote from Yonan's talk states the basic premise incredibly well. Getting two computers to work together over the Internet is a difficult feat, but making two different computer networks be securely connected together via the public Internet is pure genius. By connecting different locations over the Internet, many companies cut out the cost of dedicated circuits from the phone companies. Some companies have saved thousands of dollars by getting rid of their Integrated Services Digital Network (ISDN) lines, too. Once thought of as the high-speed (128,000 bits per second, or 128 kbs) Holy Grail, it is now utilized mainly by videoconferencing systems that require a direct sustained connection, but the two endpoints aren't usually known too much prior to the connection requirement. The ISDN lines are often referred to as glorified fast dial-up connections. Some companies utilize multiple ISDN connections to get higher-quality voice or video.

Not all VPNs had security in the early days. Packets of information were transmitted as cleartext and could be easily seen. To keep the network systems secure, the information must be encrypted. Throughout the past 25 years, different encryption schemes have gained and lost favor. Some are too easy to break with the advanced speed of current computers; others require too much processing power at the router level, thus making their implementation expensive. This is one of those areas where an early technology seemed too expensive, but through time and technological advancements, the hardware processing power has caught up with requirements of the software. Encryption that seems secure in our current environments is often insecure as time passes. With supercomputers doing trillions of computations a second, we are required to make sure that the technology employed in our networks is up to the task. There are many different types of encryption, as discussed later in the chapter.

Early in the VPN life-cycle, the goal for organizations was to connect different places or offices to remote computer systems. This was usually done with a dedicated piece of hardware at each site. This "point-to-point" setup allowed for a secure transmission between two sites, allowing users access to computer resources, data, and communications systems. Many of these sites were too expensive to access, so the advent of the point-to-point systems allowed access where none existed. Now multinational companies set up VPNs to access their manufacturing plants all over the world.

Accounting, order entry, and personnel databases were the big driving forces for disparate locations to be connected. Our desire to have more and more information and faster and faster access to information has driven this trend. Now individuals at home are connecting their computers into the corporate network either through VPN connections or SSL-VPN Web connections. This proliferation is pushing vendors to make better security, especially in unsecure or minimally secure environments. Giving remote access to some, unfortunately, makes for a target to hackers and crackers.

1. HISTORY

Like many innovations in the network arena, the telephone companies first created VPNs. ATT, with it's familiar "Bell logo" (see Figure 48.2), was one of the leading providers of Centrex systems. The goal was to take advantage of different telephone enhancements for conferencing and dialing extensions within a company to connect to employees. Many people are familiar with the Centrex systems that the phone companies offered for many years.

With Centrex the phone company did not require you to have a costly private branch exchange (PBX) switching system onsite. These PBXs were big, needed power, and cost a bundle of money. By eliminating the PBX and using the Centrex system, an organization could keep costs down yet have enhanced service and flexibility of the advanced phone services through the telephone company PBX.

The primary business of the phone companies was to provide voice service, but they also wanted to provide data services. Lines from the phone company from one company location to another (called *leased lines)* offered

FIGURE 48.2 ATT logo; the company was often referred to as Ma Bell.

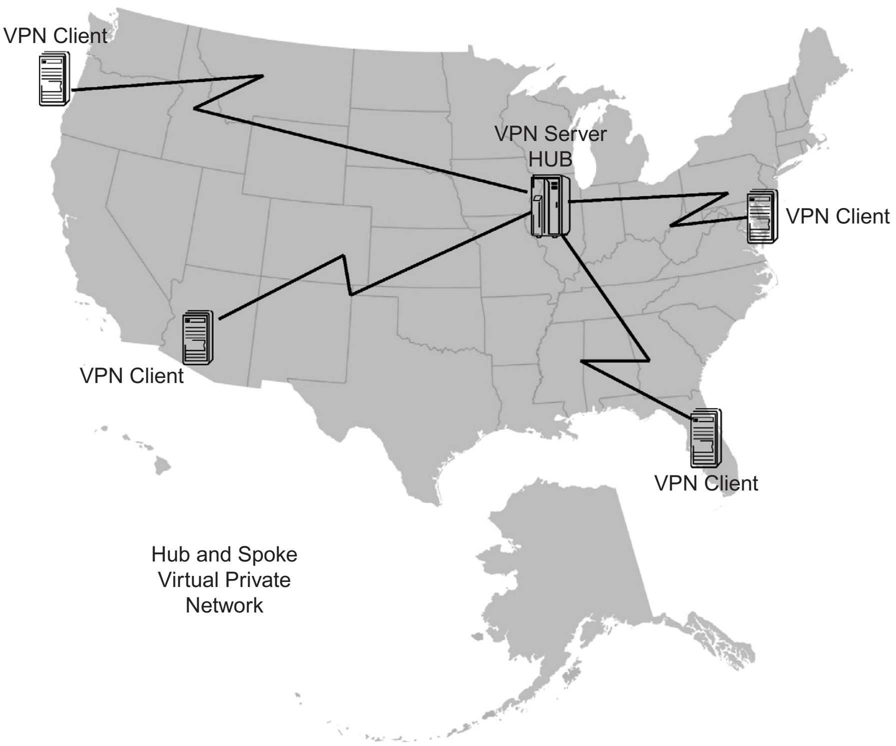

FIGURE 48.3 The hub in the early days.

remote data access from one part of a company to another.

Many companies started utilizing different types of software to better utilize their leased lines. In the early days, the main equipment was located centrally, and all the offices connected to the "hub" (see Figure 48.3). This was a good system and many companies still prefer this network topography, but times are changing. Instead of having a hub-and-spoke design, some companies opted to daisy-chain their organization together, thus trying to limit the distance they would have to pay for their leased lines. So a company would have a leased line from New York to Washington, D.C., another from D.C. to Atlanta, and a third from Atlanta to Miami. This would cut costs over the typical hub-and-spoke system of having all the lines go through one central location (see Figure 48.4).

With the proliferation of the Internet and additional costs for Internet connections and leased-line connections, the companies pushed the software vendors to make cheap connections via the Internet. VPNs solved their problems and had a great return on investment (ROI). Within a year, the cost of the VPN equipment paid for itself through eliminating the leased lines. Though this technology has been around for years, some organizations still rely on leased lines due to a lack of high-speed Internet in remote areas.

In 1995, IPsec was one of the first attempts at bringing encryption to the VPN arena. One of the early downfalls of this technology was its complexity and requirement for fast processors on the routers to keep up with the high bandwidths. In 1995, according to ietf.org, "at least one hardware implementation can encrypt or decrypt at about 1 Gbps."[2] Yes, one installation that cost thousands of dollars.

Fortunately, Moore's Law has been at work, and today our processing speeds are high enough to get IPsec working on even small routers. Moore's Law is named after Intel cofounder Gordon Moore, who wrote in 1965: "the number of transistors on a chip will double about every two years."[3] This doubling of chip capacity allows for more and more computing to be done.

Another issue with early IPsec is that it is fairly inflexible, with differing IP addresses. Many home and home office computers utilize dynamic IP addresses. You may get a different IP address each time you turn on your computer and connect to the Internet. The IPsec connection will have to be reestablished and may cause a hiccup in your transmissions or the requirement that a password be reentered. This seems unreasonable to most users.

Another difficulty is the use of Network Address Translation (NAT) for some networks. Each computer on the network has the same IP address as far as the greater

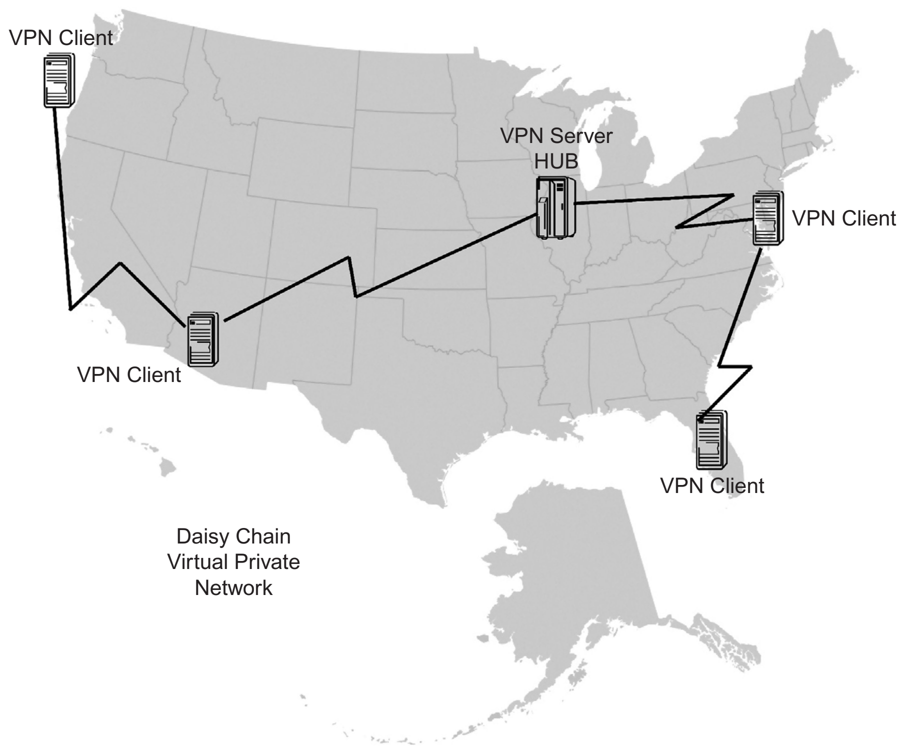

FIGURE 48.4 One central location for the hub-and-spoke system.

Internet is concerned. This is in part because of the shortage of legal IP addresses available in the IPv4 or higher address space. As we move closer and closer to the IPv6 or higher address space model, some of these issues will be moot, for a while. Soon, every device we own, including our refrigerators, radios, and heating systems, will have a static IP address. Maybe even our kitchen sinks will. Big Brother is coming, but won't it be cool to see what your refrigerator is up to? Want that ice cold beer a bit cooler, get on your Smartphone and tell the refrigerator you are on your way!

In the late 1990s Linux began to take shape as a great test environment for networking. A technology called *tun,* short for *tunnel,* allows data to be siphoned through the data stream to create virtual hardware. From the operating system perspective it looks like point-to-point network hardware, even though it is virtual hardware. Another technology, called *tap,* looks like Ethernet traffic but also uses virtual hardware to fool the operating system into thinking it is real hardware.

These technologies utilize a program running in the user area of the operating system software in order to look like a file. They can read and write IP packets directly to and from this virtual hardware, even though the systems are connected via the public Internet and could be on the other side of the world. Security is an issue with the tun/tap method. One way to build in security is to utilize the Secure Shell protocol (SSH) and transport the data via a User Datagram Protocol (UDP) or Transmission Control Protocol (TCP) packet sent over the network.

It is important to remember that IP is an unreliable protocol. There are collisions on all IP networks; high traffic times give high collisions and lost packets, but the protocol is good at resending the packets so that eventually all the data will get to its destination. On the other hand, TCP is a reliable protocol. So, like military and intelligence, we have the added problem of a reliable transportation protocol (TCP) using an unreliable transportation (IP) method.

So, how does it work if it is unreliable? Well, eventually all the packets get there; TCP makes sure of that, and they are put in order and delivered to the other side. Some may have to be retransmitted, but most won't and the system should work relatively quickly.

One way that we can gain some throughput and added security is by utilizing encapsulation protocols. Encapsulation allows you to stuff one kind of protocol inside another type of protocol. The idea is to encapsulate a TCP packet inside a UDP packet. This forces the application to worry about dropped packets and reliability instead of the TCP network layer, since UDP packets are not a reliable packet protocol. This really increases speed, especially during peak network usage times.

So, follow this logic: The IP packets are encrypted, then encapsulated and stored for transport via UDP over

the Internet. On the receiving end the host system receives, decrypts, and authenticates the packets and then sends them to the tap or tun virtual adapter at the other end, thus giving a secure connection between the two sides, with the operating system not really knowing or caring about the encryption or transport methods. From the OS point of view, it is like a data file being transmitted; the OS doesn't have to know that the hardware is virtual. It is just as happy thinking that the virtual data file is real—and it processes it just like it processes a physical file locally stored on a hard drive.

OpenVPN is just one of many Open Source VPNs in use today. Google it and you will see a great example of a VPN system that employs IPsec.

IPsec is another way to ensure security on your VPN connection. IPsec took the approach that it needed to replace the IP stack and do it securely. IPsec looks to do its work in the background, without utilizing operating system CPU cycles. This is wonderful for its non-impact on servers, but it then relies heavily on the hardware.

A faster-growing encryption scheme involves Secure Socket Layer (SSL) VPN, as we talk about it later in this chapter. This scheme gives the user access to resources like a VPN but through a Web browser. The end user only needs to install the browser plug-ins to get this VPN up and working, for remote access on the fly. One example of this SSL type of VPN is LogMeIn Rescue.[4] It sets up a remote control session within the SSL layer of the browser. It can also extend resources out to the remote user without initiating a remote-control session.

Finally, the future for standardizing (Transport Layer Security) TLS-based, user-space VPNs is growing quickly. With the ability to prevent eavesdropping before the transmissions begin, future VPN session will be even more secure. In 2011, the Internet Engineering Task Force (IETF) published the latest on TLS http://tools.ietf.org/html/rfc6176. With all these schemes and more, we should take a look at who is in charge of helping to standardize the hardware and software requirements of the VPN world.

2. WHO IS IN CHARGE?

For all this interconnectivity to actually work, there are several organizations that publish standards and work for cooperation among vendors in the sea of computer networking change. In addition to these public groups, there are also private companies that are working toward new protocols to improve speed and efficiency in the VPN arena.

4. H. Alvestrand "A Mission Statement for the IETF" Network Working Group RFC3935, October 2004.

FIGURE 48.5 Logo for IETF

FIGURE 48.6 Logo for IEEE.

The two biggest public groups are the Internet Engineering Task Force (www.ietf.org; see Figure 48.5) and the Institute of Electrical and Electronic Engineers (www.IEEE.org; see Figure 48.6). Each group has its own way of doing business and publishes its recommendations and standards.

As the IEEE Web site proclaims, the group's "core purpose is to foster technological innovation and excellence for the benefit of humanity." This is a wonderful and noble purpose. Sometimes they get it right and sometimes input and interference from vendors get in the way of moving technology forward—or worse yet, vendors go out and put up systems that come out before the specifications get published, leaving humanity with different standards. This has happened several times on the wireless networking standards group. Companies release their implementation of a standard prior to final agreement by the standards boards.

The group's vision is stated thus: "IEEE will be essential to the global technical community and to technical professionals everywhere, and be universally recognized for the contributions of technology and of technical professionals in improving global conditions."[5]

The Internet Engineering Task Force (IETF) is a large, open international community of network designers, operators, vendors, and researchers concerned with the evolution of the Internet architecture and the smooth operation of the Internet. It is open to any interested

5. A. Valencia, M. Littlewood, and T. Kolar 'Cisco Layer Two Forwarding (Protocol) "L2F"' Network Working Group RFC2341 May 1998.

FIGURE 48.7 The ANSI logo.

individual. The IETF Mission Statement is documented in RFC 3935. According to the group's mission statement, "The goal of the IETF is to make the Internet work better."[6]

Finally, we can't get away from acronyms unless we include the United States Government. An organization called the American National Standards Institute (ANSI; www.ansi.org) an over 90-year-old organization with responsibilities that include writing voluntary standards for the marketplace to have somewhere to turn for standardizing efforts to improve efficiencies and interoperability (see Figure 48.7).

There are many standards for many physical things, such as the size of a light bulb socket or the size of an outlet on your wall. These groups help set standards for networking. Two international groups that are represented by ANSI are the International Organization for Standardization (ISO) and International Electrotechnical Commission (IEC).

These organizations have ongoing workgroups and projects that are tackling the various standards that will be in use in the future releases of the VPN standard. They also have the standards written for current interoperability. However, this does not require a vendor to follow the standards. Each vendor can and will implement parts and pieces of standards, but unless they meet all the requirements of a specification, they will not get to call their system compatible.

There are several IEEE projects relating to networking and the advancement of interconnectivity. If you are interested in networking, the 802 family of workgroups is your best bet. Check out www.ieee802.org.

3. VPN TYPES

As we talked about earlier, this encryption standard for VPN access is heavy on the hardware for processing the encryption and decrypting the packets. This protocol operates at the Layer 3 level of the Open Systems Interconnection (OSI) model. The OSI model dates to 1982 by the International Organization for Standardization.[7] IPsec is still used by many vendors for their VPN hardware.

IPsec

One of the weaknesses of VPNs we mentioned earlier is also a strength. Because the majority of the processing work is done by the interconnecting hardware, the application doesn't have to worry about knowing anything about IPsec at all.

There are two modes for IPsec. First, the transport mode secures the information all the way to each device trying to make the connection. The second mode is the transport mode, which is used for network-to-network communications. The latest standard for IPsec came out in 2005.

One of the downsides to IPsec is it's complexity at the Kernal level. With one buffer overflow, you can wreak havoc on the transmitted data.

L2TP

Layer Tunneling Protocol was released in 1999; then to improve the reliability and security of Point-to-Point Tunneling Protocol (PPTP), L2TP was created. It really is a layer 5 protocol because it uses the session layer in the OSI model.

This was more cumbersome than PPTP and forced the users at each end to have authentication with one another. It also has weak security, thus most implementations of the L2TP protocol utilize IPsec to enhance security.

There is a 32-bit header for each packet that includes flags, versions, Tunnel ID, and Session IDs. There is also a space for the packet size.

Because this is a very weak protocol, some vendors combined it with IPsec to form L2TP/IPsec. In this implementation you take the strong, secure nature of IPsec as the secure channel, and the L2TP will act as the tunnel.

This protocol is a server/user setup. One part of the software acts as the server and waits for the user side of the software to make contact. Because this protocol can handle many users or clients at a time, some Asymmetric Digital Subscriber Line (ADSL) providers use this L2TP protocol and share the resources at the telephone central office. Their modem/routers utilize L2TP to phone home to the central office and share a higher capacity line out to the Internet.

For more information, see the IETF.org publication RFC 2661. You can delve deeper into the failover mode of L2TP or get far more detail on the standard.

6. E. Rosen A. Viswanathan, R. Callon "Multiprotocol Label Switching Architecture" Network Working Group RFC 3031 January 2001.

7. Callan, Tim "MD5 Hack Interesting, But Not Threatening", Security Focus January 5, 2009.

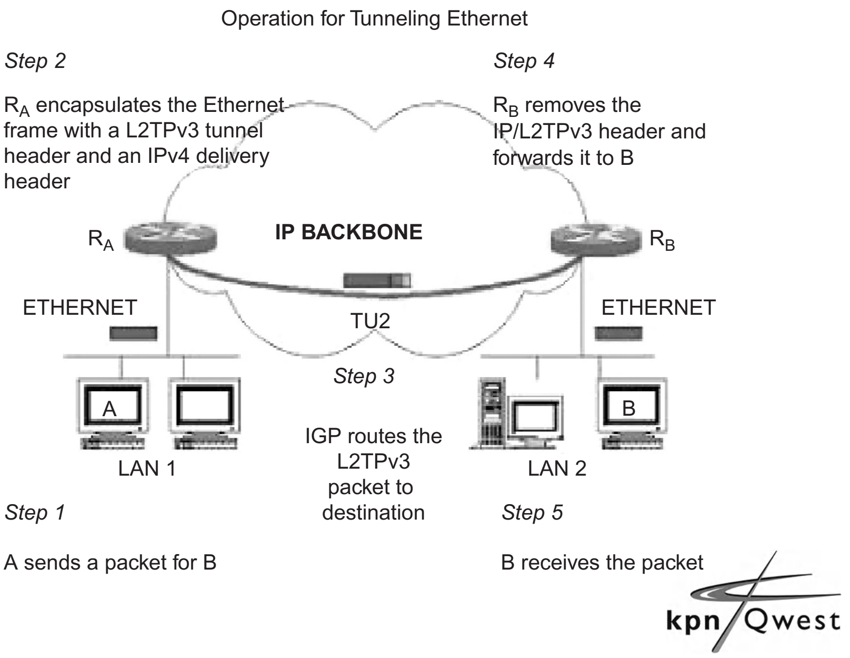

FIGURE 48.8 The operation for tunneling Ethernet using the L2TPv3 protocol.

L2TPv3 or Higher

This is the draft advancement of the L2TP for large carrier-level information transmissions. In 2005, the draft protocol was released; it provides additional security features, improved encapsulation, and the ability to carry data links other than simply PPP over an IP network (Frame Relay, Ethernet, ATM). Figure 48.8 shows the operation for tunneling Ethernet using the L2TPv3 or higher protocol and was taken from *Psuedo-wire Services and L2TPv3 or higher* from KPN/Quest.[8]

L2F

Cisco's Layer 2 Forwarding protocol is used for tunneling the link layer (layer 2 in the OSI model). This protocol allows for virtual dial-up that allows for the sharing of modems, ISDN routers, servers, and other hardware.

This protocol was popular in the mid- to late-1990s and was utilized by Shiva's products to share a bank of modems to a network of personal computers. This was a fantastic cost savings for network administrators wanting to share a small number of modems and modem lines to a large user group. Instead of having 50 modems hooked up to individual PCs, you could have a bank of eight modems that could be used during the day to dial out and connect to external resources, becoming available at night for workers to dial back into the computer system for remote access to corporate data resources.

8. ibid

For those long-distance calls to remote computer systems, an employee could dial into the office network. For security and billing reasons, the office computer system would dial back to the home user. The home user would access a second modem line to dial out to a long distance computer system. This would eliminate all charges for the home user except for the initial call to get connected. RFC 2341 on IETF.org gives you the detailed standard.[9]

PPTP VPN

Point-to-Point Tunneling Protocol was created in the 1990s by Microsoft, Ascend, 3COM and a few other vendors, in order to try and serve the user community. This VPN protocol allowed for easy implementation with Windows machines because it was included in Windows. It made for fairly secure transmissions, though not as secure as IPsec. Although Microsoft has a great deal of influence in the computing arena, the IPsec and L2TP protocols are the standards-based protocols that most vendors use for VPNs.

Under PPTP, Microsoft has implemented MPPE—Microsoft Point-to-Point Encryption Protocol, which allows encryption keys of 40 to 128 bits. The latest updates were done in 2003 to strengthen the security of this protocol. A great excerpt from Microsoft Technet for Windows NT 4.0 or higher Server explains the process of

9. Duane Dunston "In this article, Duane Dunston gives a brief introduction to OpenVPN and interviews its founder James Yonan" October 2006 Linux Security www.linuxsecurity.com/content/view/117363/49"

PPTP extremely well; check out http://technet.microsoft.com/en-us/library/cc768084.aspx for more information.

MPLS

MPLS is another system for large telephone companies or huge enterprises to get great response times for VPN with huge amounts of data. MPLS stands for MultiProtocol Label Switching. This protocol operates between layer 2 and layer 3 of the OSI model we have mentioned before. The Internet Engineering Task Force Web page with the specifications for the label switching architecture can be found at www.ietf.org/rfc/rfc3031.txt.

This protocol has big advantages over Asynchronous Transfer Mode (ATM) and Frame Relay. The overhead is lower and with the ability to have variable length data packets, audio and video will be transmitted much more efficiently. Another big advantage over ATM is the ATM requirement that the two endpoints have to handshake and make a connection before any data is ever transmitted.

The name MultiProtocol Label Switching came from the underlying way in which the endpoints find each other. The switches using this technology find their destination through the lookup of a label instead of the lookup of an IP address. Label Edge Routers are the beginning and ending points of an MPLS network. The big competitor for future network expansion is L2TPv3 or higher.

MPVPN™

Ragula Systems Development Company created Multi Path Virtual Private Network (MPVPN) to enhance the quality of service of VPNs. The basic concept is to allow multiple connections to the Internet at both endpoints and use the combination of connections to create a faster connection. So if you have a T1 line and a DS3 at your office, you can aggregate both lines through the MPVPN device to increase your response times. The data traffic will be load balanced and will increase your throughput.

SSH

This protocol lets network traffic run over a secured channel between devices. SSH uses public-key cryptography. Tatu Ylönen from Finland created the first version of SSH in 1995 to thwart password thieves at his university network. The company he created is called SSH Communications Security and can be reached at www.ssh.com (see Figure 48.9).

Utilizing public-key cryptography is a double-edged sword. If an inside user authenticates an attacker's public key, you have just let them into the system, where they can deploy man-in-the-middle hacks. Also, the intent for this security system was to keep out the bad guys at the gate. Once a person is authenticated, she is in and a regular user and can deploy software that would allow a remote VPN to be set up through the SSH protocol. Future versions of SSH may prevent these abuses.

FIGURE 48.9 SSH Communications Security logo.

SSL-VPN

Secure Socket Layer (SSL) VPN isn't really VPN at all. It's more of an interface that gives users the services that look like VPN through their Web browsers. There are many remote-control applications that take advantage of this layer in the Web browser to gain access to users' resources.

TLS

Transport Layer Security, the successor to SSL, is used to prevent eavesdropping on information being sent between computers. When using strong encryption algorithms, the security of your transmission is almost guaranteed.

Both SSL and TLS work very much the same way. First, the sessions at each endpoint contact each other for information about what encryption method is going to be employed. Second, the keys are exchanged. These could be RSA, Diffie-Hellman, ECDH, SRP, or PSK.

Finally, the messages are encrypted and authenticated, sometimes using Certificate of Authorities Public Key list. When you utilize SSL and TLS you may run into a situation where the server certificate does not match the information held in the Certificate of Authorities Public Key list. If this is the case, the user may override the error message or may choose not to trust the site and end the connection.

The whole public key/private key encryption is able to take place behind the scenes for a few reasons. During the beginning phase of the connection, the server and requesting computer generate a random number. Random numbers are combined and encrypted using the private keys. Only the owner of the public key can unencrypt the random number that is sent using their private key.

TLS is growing every year. One of the limiting factors is the size of the hash value in the final message is truncated to 96bits. So even though it could be using a 256 bit hash, the transmission cuts it to 96bits. In the future we may see something that addresses this.

4. AUTHENTICATION METHODS

Currently, usernames and passwords are the most common authentication method employed in the VPN arena. We may transport the data through an SSL channel or via a secured and encrypted transport model, but when it comes to gaining access to the system resources, most often you will have to log into the VPN with a username and password.

As we talked about earlier, there are some edge-based systems that require a dongle, and a random number is generated on gaining access to the login screen. These tiered layers of security can be a great wall that will thwart a hacker's attempt to gain access to your network system in favor of going after easier networks.

Not all authentication methods are the same. We will talk about a few different types of protection schemes and point out weaknesses and strengths.

With each type of encryption we are concerned with its voracity along with concerns over the verification and authentication of the data being sent. Transmission speeds and overhead in encrypting and decrypting data are another consideration, but as mentioned earlier, Moore's Law has helped a great deal.

Hashing

Using a computer algorithm to mix up the characters in your encryption is fairly common. If you have a secret and want another person to know the answer, but you are fearful that it will be discovered, you can mix up the letters.

HMAC

HMAC (keyed Hash Message Authentication Code) is a type of encryption that uses an algorithm in conjunction with a key. The algorithm is only as strong as the complexity of the key and the size of the output. For HMAC either 128 or 160 bits are used.

This type of Message Authentication Code (MAC) can be defeated. One way is by using the birthday attack. To ensure that your data is not deciphered, choose a strong key; use upper- and lowercase letters, numbers, and special characters. Also use 160 bits when possible.

MD5

Message Digest 5 is one of the best file integrity checks available today. It is also used in some encryption schemes, though the veracity of its encryption strength is being challenged.

The method uses a 128-bit hash value. It is represented as a 32-digit hexadecimal number. A file can be "hashed" down to a single 32-digit hex number. The likelihood of two files with the same hash is 2^{128} but with the use of rainbow tables and collision theory, there have been a few successes in cracking this encryption. As Tim Callan points out in his January 5, 2009 blog post, "Considering that it took the original researchers four tries over at least a month to successfully accomplish their attack against the RapidSSL brand, we're fully confident that no malicious organization had the opportunity to use this information against RapidSSL, or any other certificate authority authorized by VeriSign."

SHA-1

Secure Hash Algorithm was designed by the U.S. National Security Agency (NSA). There is also SHA-224, SHA-256, SHA-384, and SHA-512. The number of bits in SHA-1 is 160. The others have the number of bits following the SHA.

SHA-1 is purported to have been compromised, but the voracity of the reports has been challenged. In any case, the NSA has created the SHA-224 to SHA-512 specification to make it even more difficult to crack. At the Rump Session of CRYPTO 2006, Christian Rechberger and Christophe De Cannière claimed to have discovered a collision attack on SHA-1 that would allow an attacker to select at least parts of the message.

The basic premise is the same as the MD5 hash: The data is encrypted utilizing a message digest. This method is the basis for several common applications including SSL, PGP, SSH, S/MIME, and IPsec.

NSA is working on the next-generation SHA-3 and is seeking vendors to compete in creating the next-generation hashing algorithms. Submissions were due October 31, 2008 and the final 5 were chosen December 10, 2010. They are BLAKE, Grøstl, JH, Keccak, and Skein. The interesting thread among these, the winner will be chosen in 2013. Check the NIST website at http://csrc.nist.gov/groups/ST/hash/sha-3/index.html for the most recent updates.

5. SYMMETRIC ENCRYPTION

Symmetric encryption requires that both the sender and receiver have the same key and each computes a common key that is subsequently used. Two of the most common symmetric encryption standards are known as DES (Data

Encryption Standard) and AES (Advanced Encryption Standard). Once AES was released, DES was withdrawn as a standard and replaced with 3-DES, often referred to as Triple DES and TDES.

3-DES takes DES and repeats it two more times. So it is hashed with the 56-bit algorithm and password, and then done twice more. This prevents more brute-force attacks, assuming a strong key is used. Some VPN software is based on these symmetric keys, as we have discussed before.

Finally, a system of shared secrets allows encryption and decryption of data. This can either be done as a preshared password, which is known by both ends prior to communication, or some kind of key agreement protocol where the key is calculated from each end using a common identifier or public key.

6. ASYMMETRIC CRYPTOGRAPHY

The biggest example of asymmetric cryptography for VPNs is in the RSA protocol. Three professors at MIT, Ron Rivest, Adi Shamir, and Leonard Adelman (thus RSA), came up with the RSA encryption algorithm, which is an implementation of public/private key cryptography.

This is one of the coolest and most secure means of transmitting data. Not only is it used for transmission of data, but a person can also digitally sign a document with the use of RSA secure systems. Some states are creating systems for giving people their own digital signatures and holding the public keys in a server that can be accessed by all.

Although these systems have been around for a while, they are becoming more and more prevalent. For example, some states will allow accountants who sign up with them to transmit income tax forms electronically as long as they digitally sign the returns.

This algorithm uses two large random prime numbers. Prime number searching has been a pastime for many mathematical scientists. As the prime number gets larger and larger, its use for privacy and security systems is increased. Thus, many search for larger prime numbers. Through the use of these numbers and a key, the data is secured from prying eyes.

When you are in a public system and don't have the luxury of knowing the keys in advance, there are ways to create a key that will work. This system is very interesting and is known as the *exponential key exchange* because it uses exponential numbers in the initial key exchange to come to an agreed-on cipher.

7. EDGE DEVICES

As with any system, having two locked doors is better than one. With the advent of many remote computing systems, a new type of external security has come into favor. For instance, the setting up an edge device, allows for a unique username and password, or better yet, a unique username and a random password that only the user and the computer system knows.

These edge systems often employ authentication schemes in conjunction with a key fob that displays a different random number every 30 to 60 seconds. The server knows what the random number should be based on the time and only authenticates the person into the edge of the network if the username and password match. Once into the edge network, the user is prompted for a more traditional username and password to gain access to data, email, or applications under his username.

8. PASSWORDS

Your system and data are often only as good as the strength of your password. The weakest of passwords entails a single word or name. An attacker using common dictionary attacks will often break a weak password. For example, using the *word password* is usually broken very quickly.

Using multiple words or mixing spelling and upper- and lowercase will make your weak password a bit stronger. PasswOrd would be better. Adding numbers increases your passwords voracity. P2ssw9rd decreases your chance of getting hacked. Add in a few special characters and your password gets even more secure, as with P2#$w9rd.

But to get even stronger you need to use a password over 12 characters made up of upper- and lowercase letters, numbers, and special characters: P2#$w9rd.34HHlz. Stay away from acronyms. There are even some systems that don't allow any word from the English language to be used in any part of the password. The first time I ran into this, I was very frustrated, it is tough to teach an old dog new tricks.

Another way to keep your VPNs secure is to only allow access from fixed IP addresses. If the IP address isn't on the allowable list, you don't allow the computer in, no matter what. The unique address for each network card that is in the hardware is called the Media Access Control (MAC) address. This is another fixed ID that can be used to allow or disallow computers onto your VPN. The problem with this method is that both IP and MACs can be spoofed. So, if a person gets his hands on a valid MAC ID, he can get around this bit of security.

Some VPN systems will allow you to log in with a username and password, and then it will connect to a predefined IP address. So even if your passwords are stolen, unless the person knows the predefined IP address of the callback, they can't get into your system. This idea is a throwback to the dial-in networks that would allow a person to dial in, connect with their username and password, and then promptly disconnect and call the person's computer system back. It was an extra two minutes on the front end, but a great added level of security.

Finally, biometrics are beginning to play a role in authentication systems. For example, instead of a password, your fingerprint is used. Some systems use voiceprint, hand geometry, retinal eye scan, or facial geometry. We can foresee the day when a DNA reader uses your DNA as your password. Like a bloodhound who is able to follow you by the scent of the dead skin falling off your body (www.mythbusters.com), a sniffer device may be employed to analyze the DNA falling off your body. Homeland Security is looking into testing this technology at major airports in the U.S. I guess it beats taking naked pictures or giving you the personal pat down.

9. HACKERS AND CRACKERS

One of the inherent problems with remote access is security, Duane Dunston asked James Lonan from www.LinuxSecurity.com is "One of my major gripes with IPSec is that it adds a lot of complexity to the kernel. Complexity is really the enemy of security. The problem with putting complex security software in the kernel is that you ignore an important security principle: never design secure systems so that the failure of one component results in a catastrophic security breach. A single buffer overflow exploit in kernel space results in total system compromise – why not move the complexity into user space where the code might run in an empty chroot jail as user "nobody"? At least with this approach, a code insertion exploit can be more readily contained" (http://www.linuxsecurity.com/content/view/117363/49/).

Some good ways to prevent hackers and crackers from getting into your system is to enable the best security levels that your hardware has to offer. If you can utilize 512 or 256-bit encryption methods, then use them. If you can afford a random-number−generated edge security system, then use it.

Have your users change their VPN passwords frequently, especially if they are utilizing public Internet portals. Don't expect your local library to have the security that your own internal company has. If you access your VPN from an insecure public Internet hotspot, then make sure you change your VPN password.

Don't give out your VPN password for other people to use. This can cause you great difficulties if something sinister happens to the network and the connection is traced back to your username and password.

Another way to secure your network is to deactivate accounts that have not been used for 30 days. Yes, this can be a pain, but if a person is not regularly accessing the system, then maybe they don't need access in the first place.

Finally, remove stale VPN accounts from the system. One of the biggest problems with unauthorized VPN access is the employee who has retired but her account never got disabled. Maybe her logon and email were removed, but IT didn't remove her VPN account. Put in checks and balances on accounts.

10. MOBILE VPN

We have become a mobile computing society. We have Smartphones, iPads, Android Tablets, Netbooks, laptops, and Cars just to name a few of the things we carry that can connect to the internet. With this connectivity comes challenges to the VPN world. Having a policeman or fireman connected back to the station's computers while on the road can cause sub-nets to change, cell towers to change, phone carrier's to change not only the speed, but also the protocol for data service. Imagine having to deal with this, all while keeping a secure data connection to the office. Some vehicles are even equipped with radios that can transmit data through their own private network. Or the health professional who does well-care or sick-care visit's throughout the community and needs to enter information about their visit as they go. How does the VPN keep the connection, let alone keep it secure?

Host Identity Protocol (HIP) is the technology now being employed to keep us connected on our mobile devices. At this point there is no final standard, but the IETF (http://tools.ietf.org/html/rfc4423) is studying the technology and working with vendors to come up with a public standard. Each vendor uses this technology a little bit differently. But the market has pushed them to do so.

The basic premise is to have the tunnel bound to an IP address that is static on the phone, that static IP is used even though the tunnels change and go through different sub-nets and even different carriers. The VPN software does all the security and handshaking when the changes occur, thus leaving the user free to think they have a steady connection − no matter where they are at.

Think of some of the security risks as well as the speed problems. This harkens back to the days where an application had to be written with transmission speeds in mind, think more text, less graphics. Think re-usable graphics on different form pages, so the browser doesn't have to download them each time a page is changed.

Finally, let's briefly look at VPN deployments. Organizations planning VPN deployments should identify and define requirements, and evaluate several products to determine their fit into the organization.

11. VPN DEPLOYMENTS

VPN products vary in functionality, including protocol and application support. They also vary in breadth, depth, and completeness of features and security services. Some recommendations and considerations are included the following checklist: "An Agenda For Action For VPN Deployments").

An Agenda for Action for VPN Deployments

Some of the cryptographic requirements, including allowable hash functions and certificate key lengths have changed. Therefore, organizations who want to provide VPN services must ensure that their systems are upgradeable to the cipher suites and key lengths, and that their SSL VPN vendors guarantee that such upgrades will be available early enough for testing and deployment in the field. Thus, the following set of VPN deployments activities must be adhered to (check all tasks completed):

_____**1.** VPN manageability features such as status reporting, logging, and auditing should provide adequate capabilities for the organization to effectively operate and manage the SSL VPN and to extract detailed usage information.

_____**2.** The SSL VPN high availability and scalability features should support the organization's requirements for failover, load balancing and throughput.

_____**3.** State and information sharing is recommended to keep the failover process transparent to the user.

_____**4.** VPN portal customization should allow the organization to control the look and feel of the portal and to customize the portal to support various devices such as personal digital assistants (PDA) and smart phones.

_____**5.** SSL VPN authentication should provide the necessary support for the organization's current and future authentication methods and leverage existing authentication databases.

_____**6.** VPN authentication should also be tested to ensure interoperability with existing authentication methods.

_____**7.** The strongest possible cryptographic algorithms and key lengths that are considered secure for current practice should be used for encryption and integrity protection unless they are incompatible with interoperability, performance and export constraints.

_____**8.** SSL VPNs should be evaluated to ensure they provide the level of granularity needed for access controls.

_____**9.** Access controls should be capable of applying permissions to users, groups, and resources, as well as integrating with endpoint security controls.

_____**10.** Implementation of endpoint security controls is often the most diverse service among VPN products.

_____**11.** Endpoint security should be evaluated to ensure it provides the necessary host integrity checking and security protection mechanisms required for the organization.

_____**12.** Not all SSL VPNs have integrated intrusion prevention capabilities. Those that do should be evaluated to ensure they do not introduce an unacceptable amount of latency into the network traffic.

12. SUMMARY

This chapter assisted organizations in understanding VPN technologies and in designing, implementing, configuring, securing, monitoring, and maintaining SSL VPN solutions. The chapter also provided a phased approach to VPN planning and implementation that can help in achieving successful SSL VPN deployments. It also provided a comparison with other similar technologies such as IPsec VPNs and other VPN solutions.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? All VPNs had security in the early days.
2. True or False? ATT, with it's familiar "Bell logo," was one of the leading providers of Centrex systems.
3. True or False? In the early days, the main equipment was located locally, and all the offices connected to the "hub."
4. True or False? The encryption standard for VPN access is heavy on the software for processing the encryption and decrypting the packets.
5. True or False? Secure Socket Layer (SSL) VPN is really VPN.

Multiple Choice

1. What is another system for large telephone companies or huge enterprises to get great response times for VPNs with huge amounts of data?
   A. PPTP VPN
   B. L2F
   C. MPLS
   D. L2TPv3
   E. L2TP
2. What allows multiple connections to the Internet at both endpoints and use the combination of connections to create a faster connection?
   A. MPLS

   B. SSH
   C. MPVPN
   D. SSL-VPN
   E. TLS
3. What is used to prevent eavesdropping on information being sent between computers?
   A. SSL
   B. TLS
   C. RSA
   D. ECDH
   E. SRP
4. What are two of the most common authentication methods employed in the VPN arena?
   A. Usernames
   B. Encryption
   C. Random numbers
   D. Decryption
   E. Passwords
5. What is a type of encryption that uses an algorithm in conjunction with a key?
   A. MAC
   B. HMAC
   C. MD5
   D. SHA-1
   E. DES

EXERCISE

Problem

The problem described in this exercise is how do you connect remote users to a single main office. A medium-sized organization has a large population of users that work from remote locations once to several days each week. The organization is research-oriented, and many of these users require access to a broad range of internal IT resources to conduct their research. These resources include email, calendar, file sharing services, and secure shell access on a variety of hosts. The organization already offers remote access services in the form of a host-to-gateway IPsec solution. This works successfully, but has required significant IT labor resources to install and support the client software on user hosts. The current solution also does not provide remote access for hosts based in public locations such as hotels and kiosks. So, how does the organization implement a complementary remote access architecture?

Hands-On Projects

Project

A health care company formed from the merger of two large health care companies, started to experience a succession of network stability issues. This was a big concern for the company. Strong network availability is a crucial business requirement for the company, as it predominantly operates in a moderate client environment. If users cannot connect to the central server, they cannot access either the applications or the data that are essential for them to do their jobs. After a competitive evaluation of multiple telecommunications services, what did the company decide to do with regards to replacing its existing point-to-point connections with an Virtual Private Network (VPN)?

Case Projects

Problem

This case study illustrates how a leading building construction company needed a highly scalable and flexible telecommunications solution. So, how would the company go about meeting all of its telecommunications requirements and ensure business continuity in order to back up its vital systems in the event of an unforeseen disaster?

Optional Team Case Project

Problem

An engineering company developed a site-to-site virtual private network (VPN). How was the company's VPN solution able to cut networking costs dramatically by integrating security applications with other platform components to create a tightly-integrated, multi-layer security perimeter?

Identity Theft

Markus Jakobsson
Palo Alto Research Center

Alex Tsow[†]
The MITRE Corporation

Identity theft is commonly defined as unwanted appropriation of access credentials that allows creation and access of accounts and that allows the aggressor to pose as the victim. Phishing is a type of identity theft that is perpetrated on the Internet and that typically relies on social engineering to obtain the access credentials of the victim. Similar deceit techniques are becoming increasingly common in the context of crimeware. Crimeware, in turn, is often defined as economically motivated malware. Whereas computer science has a long-term tradition of studying and understanding security threats, the human component of the problem is traditionally ignored. In this chapter, we describe the importance of understanding the human factor of security and detail the findings from a study on deceit.

Social engineering can be thought of as an establishment of trust between an attacker and a victim, where the attacker's goal is to make the victim perform some action he would not have wanted to perform had he understood the consequences. Attackers leverage preexisting trust between victims and the chosen false identities to spur dubious actions (illegally transferring money, remailing stolen goods, installing malware on computers, and recommending fraudulent services to friends).

To understand deceit in this context, it is worth recalling that people are more likely to install software on their computer if they believe it is manufacturer-distributed patch rather than a third-party enhancement. Similarly, Internet users are more likely to visit a website when recommended by friends[1,2] and may agree to signing up to services that appear to be recommended by their friends. Moreover, when site-content hinges on accepting third-party browser extensions, friend recommendations prove highly effective in inducing the required installation.[3] When identity is used convincingly, these behaviors become social vectors for spreading crimeware and for causing users to opt in where they would not otherwise have.

Institutions and individuals project Internet identity through their Web sites and through email communication. How do attackers engineer contact with false identities? Clearly, email can be sent to anyone. Filters limit the quantity of unwanted messages, but spammers have successfully responded with increased volume and variation. Superficially, arranging contact with bogus Web sites appears to be a more difficult problem since legitimate content providers uncommonly link to spoofed Web hosts.

Roughly 50% of Web requests (by volume) are not the result of site-to-site linking, based on results from over 100,000 Internet clients hosted by the Indiana University campuses, according to the Indiana University Advanced Network Management Lab.

The other half of Web visits follow from bookmarks, direct address bar manipulation, or linking from external sources (email, word-processor documents, and instant-

messaging sessions). Social engineers influence these values through bogus links in email and by using domain names that are deceptive.

There are may studies of ways in which humans relate to deceit and treason, and there are many studies that focus on Internet security, but there is not an abundance of research on the combination of these two important fields. How do people relate to deceit on the Internet? This is an important question to ask—and to answer—for anybody who wants to improve Internet security.

1. EXPERIMENTAL DESIGN

This experiment tests the ability to identify phishing, an Internet scam that spoofs emails and Web pages to trick victims into revealing sensitive information. Although cast in terms of phishing, the results generalize to identity spoofing for purposes beyond information theft. This experiment tests the effects of several media features—sometimes in multiple contexts—on an individual's evaluation of its phishing likelihood. This experiment shows subjects six email screenshots followed by six Web page screenshots and asks them to rate their authenticity on a five-point scale: Certainly phishing, Probably phishing, No opinion, Probably not phishing, and Certainly not phishing (see Figure e49.1 for an example). The experiment was administered through SurveyMonkey.com,[4] an online Web survey service. Subjects were required to rate each screenshot before advancing to the next stimulus. The survey provided the following instructions to subjects:

- Phishing is a form of Internet fraud that spoofs emails and Web pages to trick people into disclosing sensitive information. When an email or Web page fraudulently represents itself, we classify it as phishing.
- This survey displays a sequence of email and Web site screenshots. Assume that your name is John Doe and that your email address is johndoe1972@gmail.com. Please rate each screenshot's authenticity using the five-point scale: Certainly phishing, Probably phishing, No opinion, Probably not phishing, Certainly not phishing.

This style of testing, termed *security first*, measures fraud-recognition skills rather than habits. Subjects are not trying to accomplish other work but are merely instructed to rate a series of legitimate and illegitimate stimuli. For this reason, security-first measurements place a plausible upper bound on fraud detection habits in normal computer usage. Even though security-first

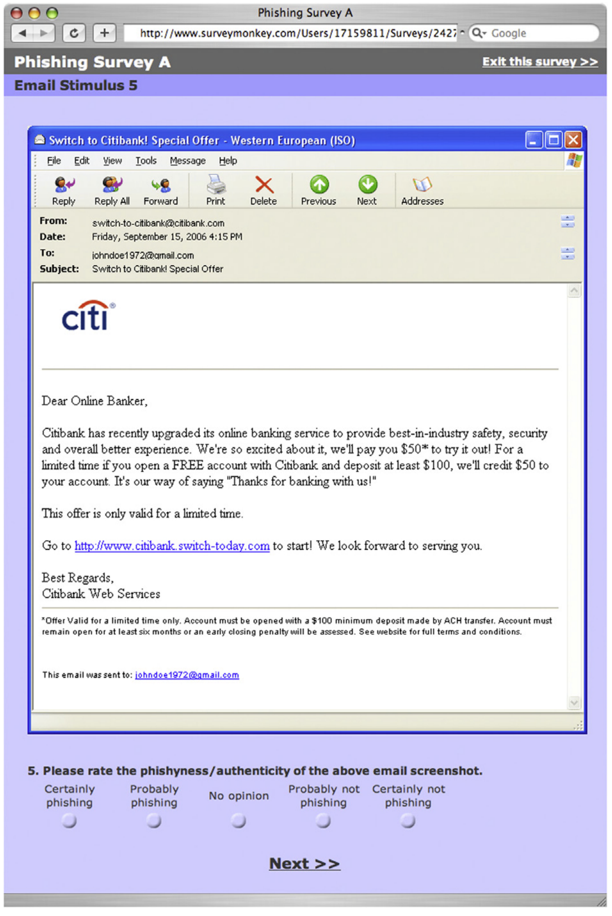

FIGURE e49.1 Subjects evaluate authenticity based on Screenshots using a five-point scale. The survey required a judgment before proceeding to the next stimulus.

evaluations have shown high susceptibility to phishing,[5,6] role-playing experiments designed to measure fraud detection habits[7,8] demonstrate even more serious vulnerability.

Subjects were recruited from an undergraduate introductory noncomputer-science-major class on computer usage and literacy. Of a class size exceeding 600 students, 435 began this study. All but 12 subjects were between

17 and 22 years old; the gender split was 40.0% male to 57.9% female (2.0% did not respond to this question). Although the test population is not demographically representative of general computer users, their enrollment in the introductory course suggests that their computer skill level is generally representative. The class's only prerequisite is high-school algebra. Almost all students in this class had used computers before but had no particular expertise.

The experiment divided the population into two sets through random selection. The two sets completed different versions of the survey. For 10 of the stimuli, the two versions differ only by a target collection of test features. Our primary analysis compares the impact of the feature changes, by using the χ[9] to represent the difference between response distributions. In two other question sets, subjects evaluate the authenticity of messages and Web pages under third-party administration (a potential vector for social engineering). We further designed the test to simulate a roughly equal number of authentic and phishing stimuli to avoid effective use of a trivial rating strategy: If there were significantly more phishing stimuli than authentic stimuli, subjects could employ an "always phishing" strategy that would correctly evaluate most of the stimuli without exercising due consideration.

Since the stimuli are only screenshots, their inauthentic features were designed to be evident on examination (rather than mouse-over or source analysis). For instance, incorrect domains are apparent in email hyperlinks; they are not disguised by an inconsistent *href* attribute. The domains we chose to simulate inauthentic URLs were not in use at the time of testing, but some are owned by their respective companies, others are owned by unrelated companies, and the rest appear to be unregistered, according to the Whois database. Our use of these domains as representations of inauthentic URLs is still valid because none of these URLs exist with the content we present. We outline the stimuli, their relevant features, and what we hope to learn in Figures e49.2a and e49.2b.

Authentic Payment Notification: Plain versus Fancy Layout

These two email messages use actual payment notification text from Chase Bank (see sidebar, "A Strong Phishing Message"). The text personalizes its greeting and references a recent payment transaction; there are no hyperlinks. One version uses the original layout (a one-color header containing the company logo followed by the message text); the other version uses an enhanced layout (a header that includes a continuous tone shiny logo and a photograph of a satisfied customer, a smooth gradient footer graphic that spans the page with a gentle concave arch, hyperlinks to Privacy and Terms of Use, and a copyright notice; these graphics were adapted from the Web page at www.bankone.com).

A Strong Phishing Message

Dear John Doe,

JPMorgan Chase & Co. is proud to serve you as a former Bank One client.

Chase Online's patented ePIN technology is used both for eDebit transactions and for physical ATM access. While we will support the legacy 4 digit PIN for the remainder of the year, until December 31, 2006, we invite you to register for the ePIN program through our secure online server:

https://www.chase.ePIN-simplicity.com

If you have any questions about this or other Chase programs, do not hesitate to call our toll-free customer service number, 1-877-CHASEPC.

Sincerely,

Client Services

JPMorgan Chase & Co.

Strong Phishing Message: Plain Versus Fancy Layout

We constructed the phishing message text to sound as plausible as possible. Opening with a personalized greeting, the message explains that former Bank One customers will need to register for Chase's ePIN program—a replacement for ATM PINs that is also bundled with a new eDebit online service. It implicitly threatens service discontinuation by supporting "legacy 4 digit PINs for the rest of the calendar year." The bogus registration hyperlink uses the made-up URL https://www.chase.ePIN-simplicity.com. The message closes with a bogus phone number to call for assistance. The two versions of this message use the same plain and fancy layout schema described earlier, with one exception: The fancy layout adds shiny letters proclaiming "Bank One is now Chase" (see Figure e49.3) between the header and message text.

Authentic Promotion: Effect of Small Footers

Figure e49.4 shows an authentic message from the AT&T Universal card that promotes the company's paperless billing system. It personalizes the greeting and includes the last four digits of the account number. There are multiple company logos, a blue outline around text, an Email

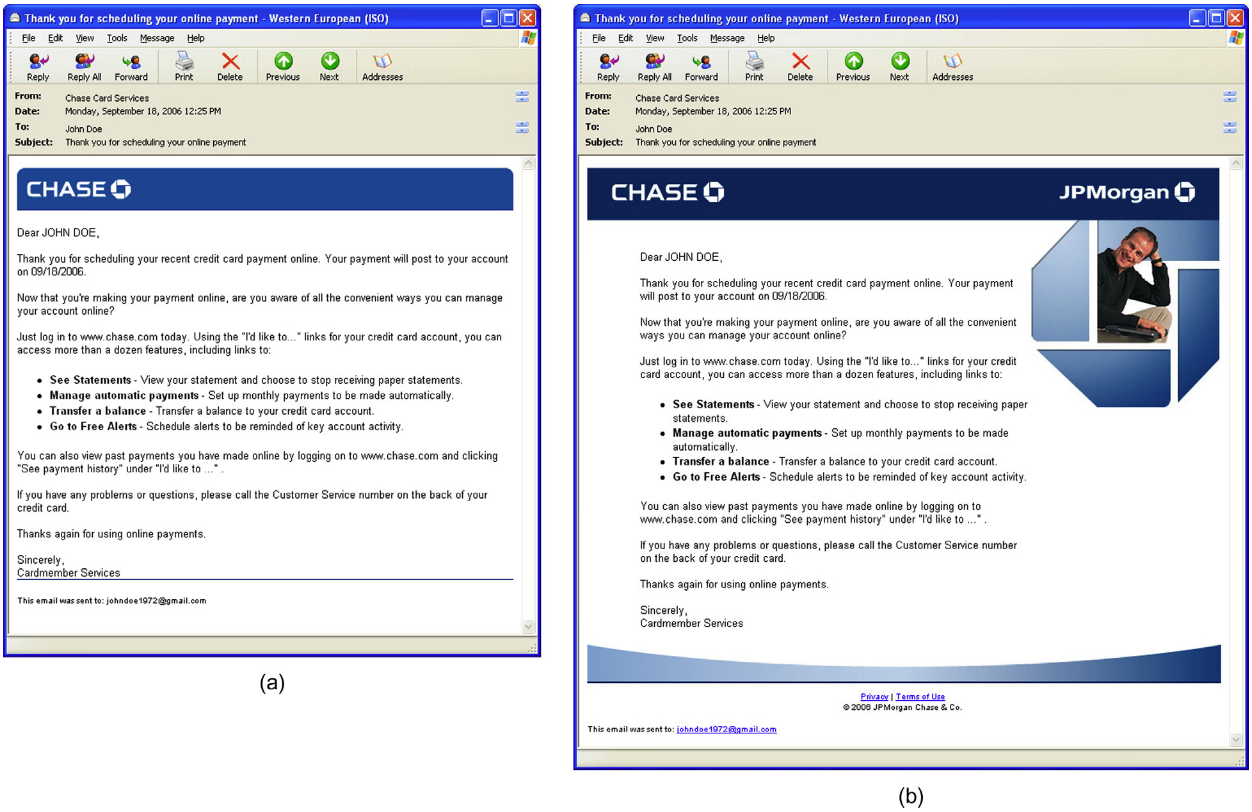

FIGURE e49.2 (a) Plain layout. (b) fancy layout.

Security Zone box, and a small-print footer filled with trademark, copyright, and contact notices as well as various informational and administrative hyperlinks. The principal login hyperlink conceals its destination. The test pair consists of the original message and a modified version that excludes the small print footer.

Weak Phishing Message

The sidebar "Phishing Message" shows a phishing message promising $50 for opening an account with Citibank. There is a simple company logo in the header; a footer contains legal disclaimers about the offer. There is no personalization, and the lone hyperlink is a made-up domain (actually owned by an unrelated organization), http://www.citibank.switch-today.com. Figure e49.5 contains its screenshot. The two versions differ only by the presence of a center-aligned "VeriSign Secured" endorsement logo that follows the footer's legal disclaimers.

Authentic Message

The test determines the impact of a "VeriSign Secured" logo added to the footer of an authentic message, as shown in Figure e49.6. The notice begins with a personalized greeting and informs the client about changes in PayPal's logo insertion policy. The message body is considerably longer than all of the other messages except for

Phishing Message

Dear Online Banker,

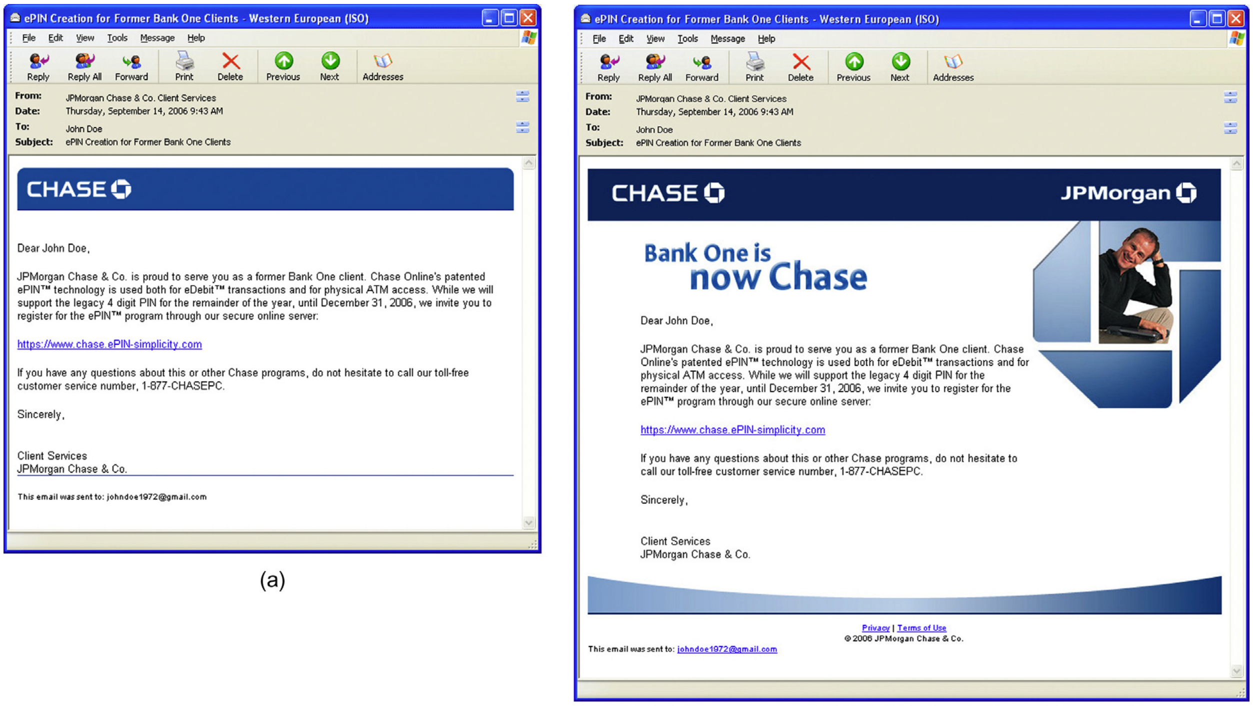
Citibank has recently upgraded its online banking service to provide best-in-industry safety, security and overall better experience. We're so excited about it, we'll pay you $50* to try it out! For a limited time if you open a FREE account with Citibank and deposit at least $100, we'll credit $50 to your account. It's our way of saying "Thanks for banking with us!"

This offer is only valid for a limited time.

Go to http://www.citibank.switch-today.com to start! We look forward to serving you.

Best Regards,
Citibank Web Services

*. Offer valid for a limited time only. Account must be opened with $100 minimum deposit made by ACH transfer. Account must remain open for at least six months or an early closing penalty will be assessed. See website for full terms and conditions.



(a)

(b)

FIGURE e49.3 (a) Using a plain layout schema (b) using a fancy layout schema; and (c) using a plain and fancy layout schema.

the Netflix stimulus. The primary message contains no hyperlinks, but their small-print footer furnishes a hyperlink to unsubscribe from their newsletter. One interesting feature of the message is a boldfaced statement: "If you do not wish to have PayPal automatically inserted in your listings, you must update your preferences by 9/25." Though genuine, this message parallels the account shutdown threats brandished by many phishing messages. The header contains a monochrome company logo and a two-tone horizontal separation bar.

Login Page

We say that the URL is strongly aligned with the content of the page when these two "belong together." Imagine that one would look at some ten Web pages (without associated URLs), and then some ten randomly ordered URLs, each one belonging to one of the ten Web pages. The easier it is for a potential reader to correctly pair up Web pages and URLs, the stronger the alignment. If any Web page and associated URL is not correctly matched up, then the alignment is very weak.

Let's now turn to an example, as shown in Figure e49.7. This browser's content window displays an exact copy of the AT&T Universal card login page. Like most Web login pages, it displays a high level of layout sophistication: photographs of happy clients, navigation bars, product pictures, a sidebar, promotional windows, and small-print legal disclaimers. It also displays a "VeriSign Secured" site endorsement logo. The two versions of this stimulus differ by their address bar contents: version (a) uses https://www.accountonline.com/View?docId = Index&siteId = AC&langId = EN and consequently displays a browser frame padlock; version (b) uses the unencrypted URL http://www.attuniversalcard.com/ (owned by AT&T but not in use).

Login Page: Strong and Weak Content Alignment

This next set takes the alternative approach to aligning the address bar URL with content: change the content. Both pages (see Figure e49.8) use the unregistered URL www.citicardmembers.com/. Version (a) displays a precise copy of the authentic Citi Credit Cards login page in its content window, whereas the version (b) content window displays modified logos and links (see Figure e49.9) for better alignment with the URL.

Figures 49.8a and 49.8b use a sophisticated layout with nearly all the same identifiable features of the AT&T Universal Card login: photographs of happy clients, navigation bars, product pictures, sidebars, promotional windows, and the "VeriSign Secured" logo.

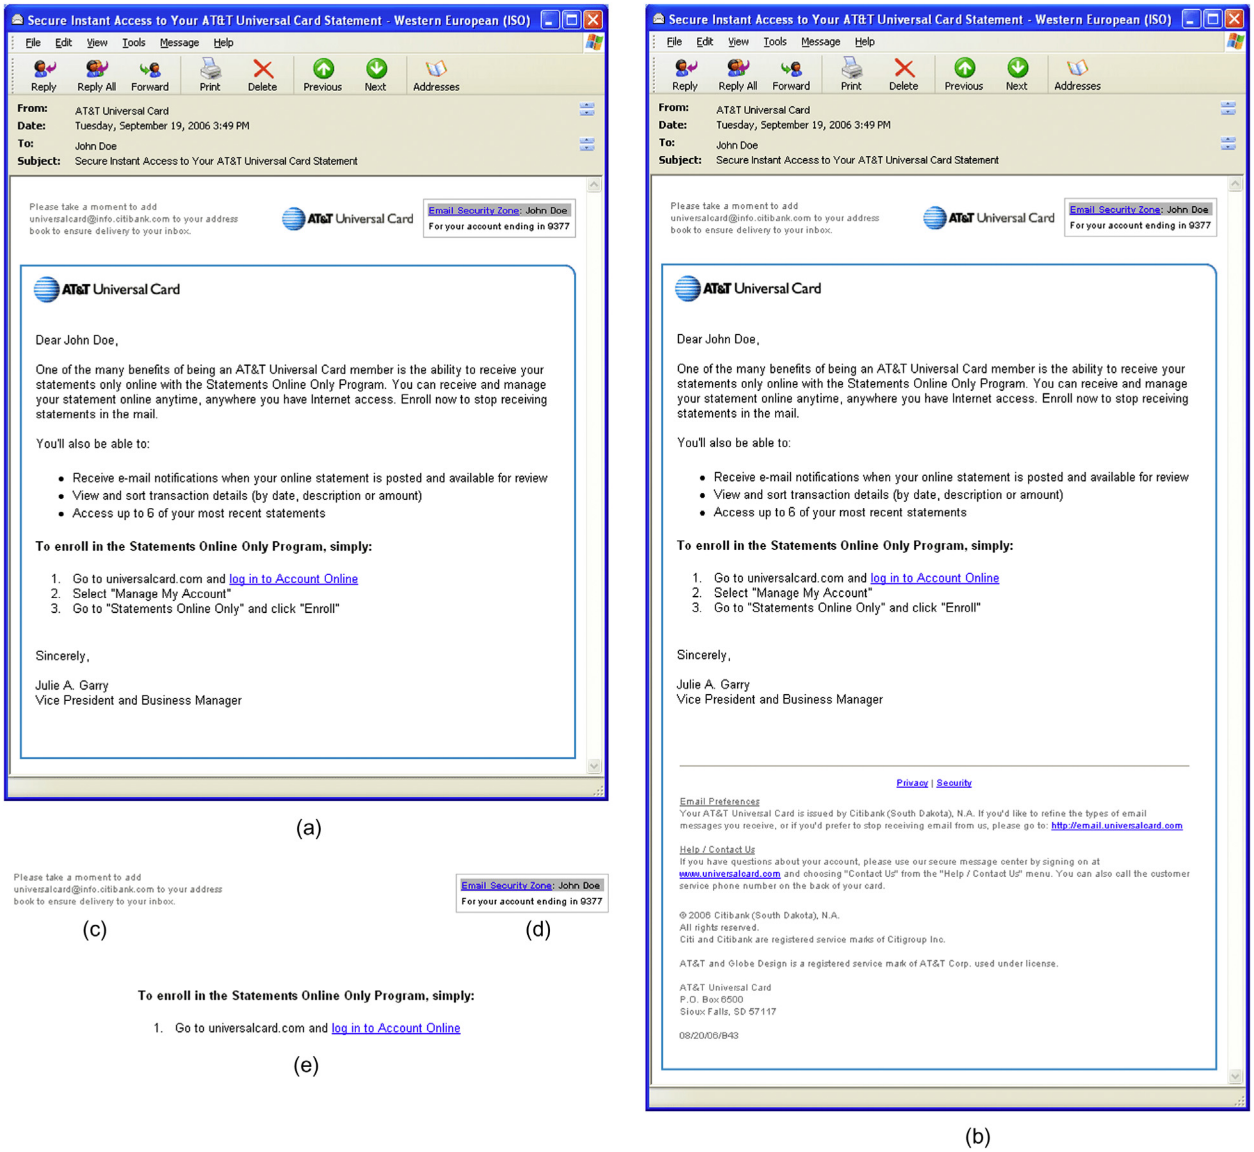


FIGURE e49.4 (a) An authentic message from the AT&T Universal card that promotes the company's paperless billing system. (b) an authentic message from AT&T Universal card that personalizes the greeting and includes the last four digits of the account number; (c) header detail left side; (d) header detail right side; and (e) hyperlink detail.

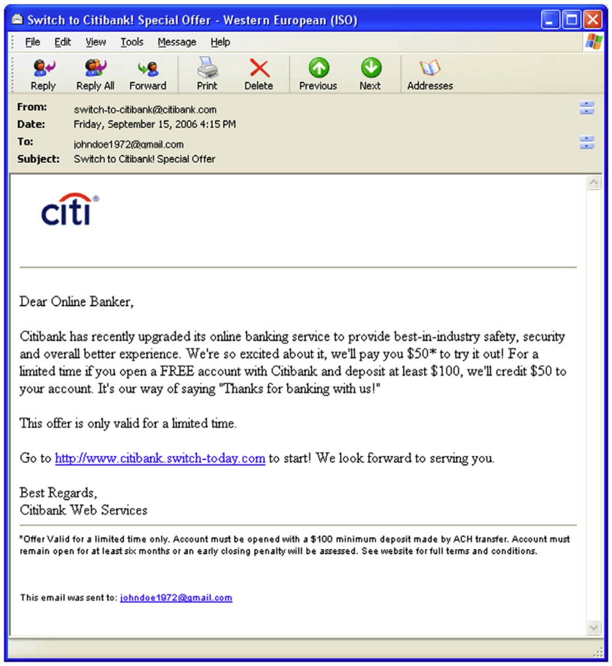
Login Page: Authentic and Bogus (But Plausible) URLs

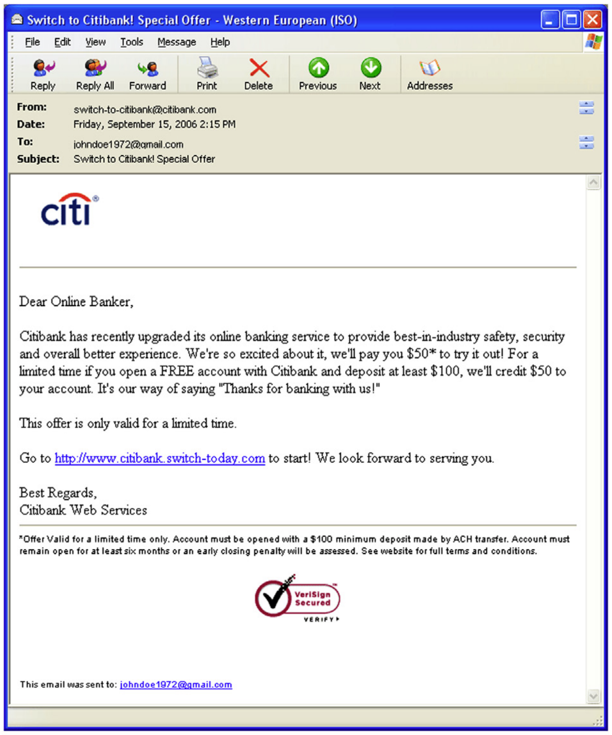
These two stimuli test the impact of changing a well-aligned authentic URL (see Figure e49.9), http://www.paypal.com/ebay, to a reasonably well-aligned bogus URL, http://www.ebaygroup.com/paypal (domain owned by eBay but not in use). The main content window is the same for both: The eBay decorated version of the PayPal login page, which contains an eBay logo to the lower right of the primary PayPal logo. The page layout contains all the main features of the previous login pages but includes a more thorough set of third-party endorsement logos: "VeriSign Secured," "Reviewed by TRUST-e," and "Privacy: BBB OnLine." SSL is not used in either stimulus.

Login Page: Hard and Soft Emphasis on Security

Figure e49.10 tests whether it is possible to undermine confidence in an authentic login page with excessive concern about security and online fraud. These two stimuli represent an extreme but real-world case. Clients of the



(a)



(b)

FIGURE e49.5 (a) Effect of endorsement logo. (b) center-aligned "VeriSign Secured" endorsement logo.

Indiana University Employees Federal Credit Union (IUCU) were targeted by a phishing attack in early August 2006. In response, the credit union altered its Web page to include a large banner, as shown in Figure e49.10f.

They further augmented the news section with a similar message: "Warning! Phishing Scam in progress (learn more)." Finally, a section named "Critical Fraud Alerts" contained the exact same warning as the one from the news section. The twin page eliminates all phishing warnings (including the banner) and changes the "Critical Fraud Alerts" section heading to read "Fraud Prevention Center." Generally, the language was changed to sound "in control" rather than alarmist.

Bad URL, with and without SSL and Endorsement Logo

Can an endorsement logo and SSL padlock overcome a bad domain name? This next set, as shown in Figure e49.11, tests these two features on a Wells Fargo phishing site based on the bogus domain www-wellsfargo.com. The login page is similar in layout to the others but does not feature photographs of people. The only continuous tone graphic is an image of a speeding horse-drawn carriage that evokes a Wild West money transfer service. One screenshot contains the original page content using an unencrypted connection; the other stimulus uses SSL and adds a center-aligned "VeriSign Secured" logo to the page's footer.

High-Profile Recall Notice

At the time of testing (10/02/2006–10/12/2006), the press had been alive with recent reports[10] of laptop battery recalls from both Dell and Apple. Sony, the source of the batteries, ultimately issued a direct recall for the same batteries, by adding several more brands on 10/23/2006.

As shown in Figure e49.12, this test set does not follow the controlled-pair format of the previous stimuli. One stimulus is a screenshot of the official Dell Battery Return Program Web page. The page layout is substantially simpler than all other Web stimuli. A four-color header logo adorns the top of the page. It presents the content as a letter to "Dell Customer," explaining the danger and how to determine eligibility for exchange. Notably, there is a single column of content, no photos, and no promotional content of any kind. They use the third-party domain dellbatteryprogram.com. Use of this

10. D. Darlin, "Dell will recall batteries in PCs," *New York Times*, 15 August 2006, http://select.nytimes.com/search/restricted/article?res = F10A1FF83C5A0C768DDDA10894DE404482.

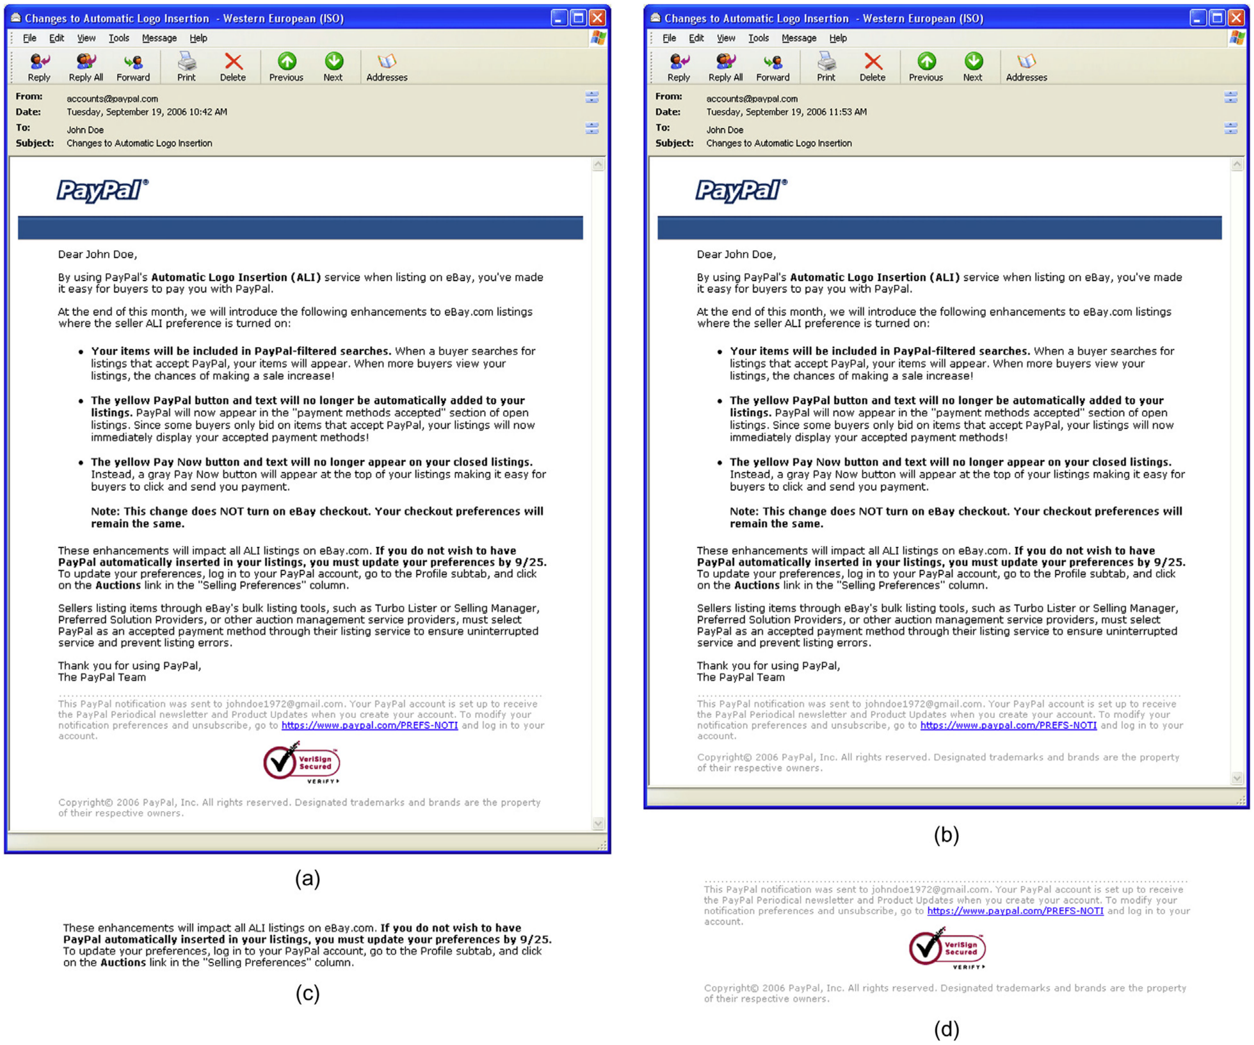


FIGURE e49.6 (a) "VeriSign Secured" logo added to the footer of an authentic message. (b) authentic message—effect of endorsement logo; (c) shared body detail; (d) endorsement footer detail.

domain for the official page makes the replacement service ripe for phishing.

We constructed a phishing email message using the header, footer, and textual content from this Web page. The phishing message omits the middle section on how to identify eligible batteries and instead requests that the recipient go to the bogus Web page at http://www.dellbatteryreplacements.com.

Low-Profile Class-Action Lawsuit

As shown in Figure e49.13, this last set of stimuli also follows the third-party email and Web page form of the previous set. Both stimuli are authentic, but they use altered dates to appear relevant at the time of testing. The email message is a lengthy notice that describes a class-action lawsuit against Netflix, a settlement to the lawsuit, and options for claiming benefits. There is no greeting, signature, color, or graphics. The only hyperlinks direct the user to the authentic third-party URL, http://www.netflixsettlement.com. The Web page has a similarly bare appearance but with much less text. It behaves as a hyperlink gateway for more information under the URL http://www.netflix.com/settlement/ (the result of redirection from http://www.netflixsettlement.com).

2. RESULTS AND ANALYSIS

Our experiment directly controls for the effect of several design features. There are some surprises in the direct results from these tests, including the stunning impact of a detailed small print footer on an otherwise well-conceived legitimate message; however, the experiment reveals an unexpected, but in retrospect obvious, lesson

(a)

(b)

(c)

FIGURE e49.7 (a) Strong and weak URL alignment; (b) weak alignment URL detail; (c) strong alignment URL detail.

about email messages: The "story" of the message is critical. Messages with strong and succinct narrative components rated highly and their ratings appear to be less susceptible to changes in graphic design. On the other hand, authenticity perception changed significantly for messages that say little (such as a service promotion) under document feature variances. Two of the five sets of "twins" did not change significantly, according to the metric, when augmented with the very same features that produced significant changes in other messages. Subjects judged these messages principally on their narrative content.

The Chase phishing message uses the company's recent acquisition of Bank One as a pretext for imminent service change to ATM card authentication; the story further bundles this change with the addition of a new service, eDebit, and implicitly threatens discontinuation of service by claiming to "support the legacy 4 digit PIN for the remainder of the year." This consequence is much less direct than the standard "Your account will be suspended in 48 hours if . . ." strategy used by many phishers. It works on a less urgent time scale and is pitched as a convenience to all clients rather than an anomaly specialized to a specific client. There was no significant difference in subject evaluation between the plainly formatted version of this message with the monochrome corporate header and the one with several customized continuous tone graphics.

Yet these same graphics, minus the shiny "Bank One is now Chase" banner, produced a significant change ($p = 0{:}018$) in evaluations of Chase's authentic payment notice. The payment notice thanks the receiver for a recent online payment, then goes on to inform the user about features of their online account management interface. In terms of relevance, there is less potential impact on the user. Ignoring this message won't expose the client to any changes (good or bad). Assuming that the name and recent online interaction are correct, the message communicates little that would surprise the average client. So, in place of strong narrative components, the subject looks to formatting cues to further inform confidence. This message rated highly in its simple form and was pushed higher by the improved graphics. We attribute its initially high rating to its exclusion of hyperlinks, informative nature, and well-contextualized message.

Subject reactions to the presence of the "VeriSign Secured" logo differed dramatically between the two test messages. One message, a change of policy notice from PayPal, experienced no statistical difference in subject evaluations of its endorsed and unendorsed forms. The policy change notice shares several narrative features with the Chase phishing message: Both messages have a customized salutation, both inform users about an institution wide change (in this case, the particulars of their logo insertion policy), and both claim that inaction will result in a change of service. The PayPal message has no hyperlink in the message body but does contain a link in its small-font gray footer to manage user preferences; we think that this forecasts a potential phishing strategy.

The other message that tests the impact of the "VeriSign Secured" logo is a phishing message that exploits the Citibank brand. The experiment shows a statistically significant change in subject evaluations ($p = 0{:}047$) due to this single feature change. Of all the messages, this message makes the weakest connections to the receiver. It begins with a generic salutation. Worse, the first sentence promotes the goodness of their online service but fails to involve the receiver in any way. Not

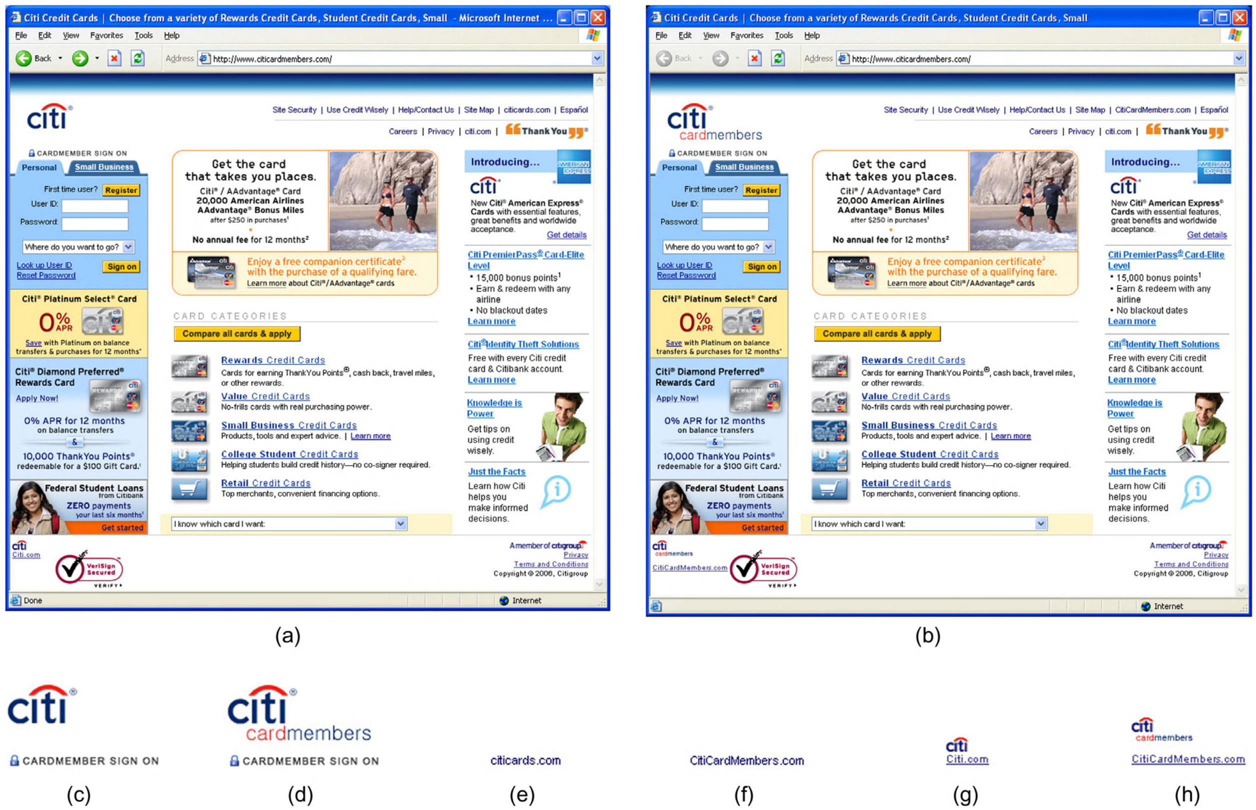

FIGURE e49.8 (a) A precise copy of the authentic Citi Credit Cards login page in its content window. (b) content window displays modified logos and links; (c) location of detail window; (d) original and modified detail window; (e) header menu of detail window; (f) Cardmember sign on detail window; (g) footer of detail window; and (h) Cardmembers of detail window.

until the second sentence does the message's relevance become evident to the reader: They are offering "$50* to try it out!" These two messages had the lowest average ranking of all the email stimuli. Ignoring this message has no impact on the user except for failing to miss out on an offer of dubious value. Ultimately, the stimulus fails to engage the reader, and so subjects base more of their evaluation on nonnarrative factors such as the endorsement logo and the bogus URL.

The Dell battery replacement program message presents a compelling story, but not directly. The incident received a high level of media coverage due to spectacular reports of exploding and burning laptop computers. The Dell message, which we manufactured, benefits from other sources spreading the story. Without this third-party validation, this message could have bordered on implausibility, but instead our subjects produced ratings that were statistically indistinguishable from the two most highly ranked email messages in the batch. This message contains a slightly nicer-than-average layout (multicolored header, footer graphic with links) but less personalization and a fraudulent (but semantically plausible) URL. The story was so powerful and present in the subjects' minds that they were willing to discount the suspicious link and generic greeting.

The other third-party attack (NetFlix) did not benefit from recent or high-profile media coverage (see Table e49.1). We may have further lowered its rating by altering the dates to appear relevant at the time of testing.

Subjects could have perceived the timeline as implausibly long (even for legal action) or may have been familiar with the case and known that the dates were incorrect. In addition to these changes, the original message is particularly poorly conceived. Though it has strong narrative elements that present lawsuit context, the elements of the settlement, and response options, the message is entirely too long. Message length and detail create an incentive for users to quickly evaluate according to nonnarrative features. The most visually obvious features are the inclusion of blue hyperlinks—the only non-black-and-white symbols—that point to http://www.netflixsettlement.com. Though this is the legitimate domain, it should raise suspicion because it is an apparent "cousin domain" to the parent company's Web site. The lack of strong design features seals its poor evaluation. There is no company header—a feature present on every other stimulus—and

FIGURE e49.9 (a) A reasonably well-aligned bogus URL. (b) logo detail; (c) bogus URL detail; and (d) authentic URL detail.

no opening salutation or signature. The contact address appears to be an afterthought that does not even specify a division of the company, let alone an appropriate administrator.

The biggest surprise of the test appears in a pair of authentic AT&T Universal card messages. In many ways, this is the polar opposite of the Netflix settlements message: it has strong design elements and a short, weak narrative. The message promotes AT&T's Statements Online Only program without bundling it with a recent action (as Chase does with its payment notification). Ignoring this message will not produce any change in the receiver's service, nor does enrolling in the program provide any obvious benefit to the client; in fact, enrollment could result in unintended late payments due to imperfect spam interdiction of electronic billing notices. What the message lacks in narrative appeal it makes up for in design strength. It customizes the message to the receiver both in the opening salutation and in an "Email Security Zone" header box that displays client name and client account number suffix. The header also has a spam awareness message and company logo. A blue outline that complements the company logo encloses the rest of the content. The corporate logo appears a second time within the blue content box and the letter opens and closes with personalized salutations: "Dear John Doe," and "Sincerely, Julie A. Garry." The two versions of this message differ in the presence of a detailed small-print footer below the signature, which contains hyperlinks to privacy and security policies, as well as hyperlinks bearing the universalcard.com domain. The footer uses a small gray font and presents text for adjusting "Email Preferences" and a "Help/Contact Us" section containing the postal address and various trademark and copyright notices.

The one ambiguous feature of this email is a centrally located hyperlink, labeled "log in to Account Online." It does not indicate the URL in the text. Phishers frequently employ this sort of hyperlinking strategy to conceal the bogus server's URL. The footer may add confidence because its hyperlinks appear to reference URLs with legitimate and semantically aligned domain names; none of the hyperlinks outside the header indicate a target domain. Alternatively, the contact, copyright, and trademark notices themselves may improve confidence in the message. It is particularly interesting that even though the footer-less message displayed the last four digits of the credit-card number, customized the greeting, and employed generally strong design elements, except for the Netflix settlement, it was still ranked lower than any other legitimate message. This supports the experimental results in[11] that indicate indifference to customized greetings in certain contexts. Yet adding the footer boosts the evaluations to the point where it is statistically indistinguishable from the other two most highly ranked messages—the Chase payment notification with fancy graphics and the Dell battery recall notice.

Web sites, particularly the login and information collection pages associated with phishing scams, do not present a story the way email messages do. For this reason, their credibility depends much more on document features and graphic design. Subjects assigned significantly

different ratings to three of the five sets of twin stimuli. The results show that address bar alignment with page content, overwrought concerns about fraud, and third-party endorsements substantively change authenticity assessments.

The biggest rating difference among the Web page stimuli was measured between the two versions of the "AT&T Universal Card Sign-on" page. The official version, which uses the address URL https://www.accountonline.com/View?docId = Index&siteId = A C&langId = EN, has the lowest average rating of the ten Web stimuli in the paired testing. With an average rating of 2.76, it rated lower than a simulated phishing Web site based on the suspiciously formed domain www-wellsfargo.com (avg. rating: 3.17). Subjects who saw the unused domain http://www.attuniversalcard.com in the address bar of the AT&T card login page rated it significantly higher ($p = 0{:}004$) than the authentic page. The page content strongly aligns with the URL text http://www.attuniversalcard.com: the phrase "AT&T Universal" appears no less than seven times on the login page, whereas the phrase "AT&T Universal Card" appears four times in the content window. Interestingly, the official page uses HTTPS and displays an SSL padlock in the

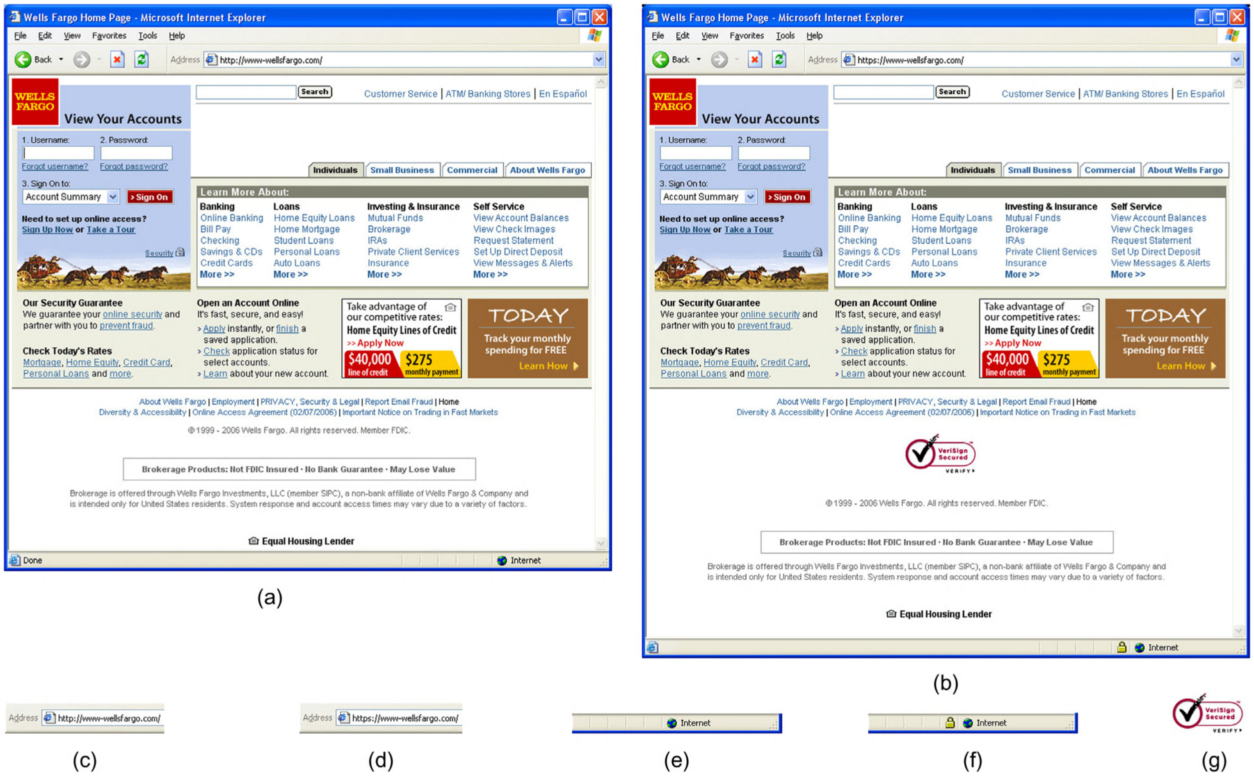

FIGURE e49.11 (a) Without SSL and endorsement logo. (b) with SSL and endorsement logo; (c) no SSL/endorsement logo; (d) SSL/endorsement detail; (e) Internet no SSL/endorsement status bar; (f) Internet SSL/endorsement status bar; and (g) VeriSign logo.

lower right-hand browser frame, whereas the attuniversalcard.com domain does not use SSL and consequently does not display the padlock on the browser frame. Subjects found the semantic alignment of the URL to be a much stronger indicator of authenticity than SSL utilization. In fairness, subjects could not examine the certificates, nor would they have been subject to the "Unable to verify the identity of host" pop-up window in the case of a self-signed certificate. Nevertheless, other user studies have found that in practice, subjects rarely consider these factors.[12,13]

Much to our surprise, the phishing simulation based on the URL www-wellsfargo.com rated significantly higher ($p = 0{:}00001$) than the official AT&T Universal card login page. Subjects valued semantic alignment between content and host domain more than domain well-formedness. Syntactically there is nothing wrong with the domain, but replacing the dot with a dash is clearly an attempt at deception. Adding SSL and a "VeriSign Secured" logo to the Wells-Fargo phishing page produced a significant improvement in authenticity ratings ($p = 0{:}029$). It's worth noting that the authentic login page (not in the test) does not display a VeriSign logo but does use SSL. In spite of subjects either failing to notice the dash-for-dot exchange or not thinking that it was suspicious, they did notice the presence of either SSL or the VeriSign logo. Note that the AT&T login page also used SSL and displayed a VeriSign endorsement, but neither of these features could overcome the mistrust of the accountonline.com domain.

The last statistically significant difference between twins in the Indiana University Credit Union homepage ($p = 0{:}022$) shows that too much concern about security can reduce customer confidence. Subjects responded positively to use of less fearful language and rated the softer, more constructive content significantly higher than the page that displayed stark warnings. Note that correct domain names and SSL were used on both stimuli. This is a case where a good-faith effort to educate clients about phishing undermines confidence in the Web site's authenticity. Login pages are no place for fear-provoking messages.

One way phishers align page content with URLs is by choosing an apt domain name; the other way is to change

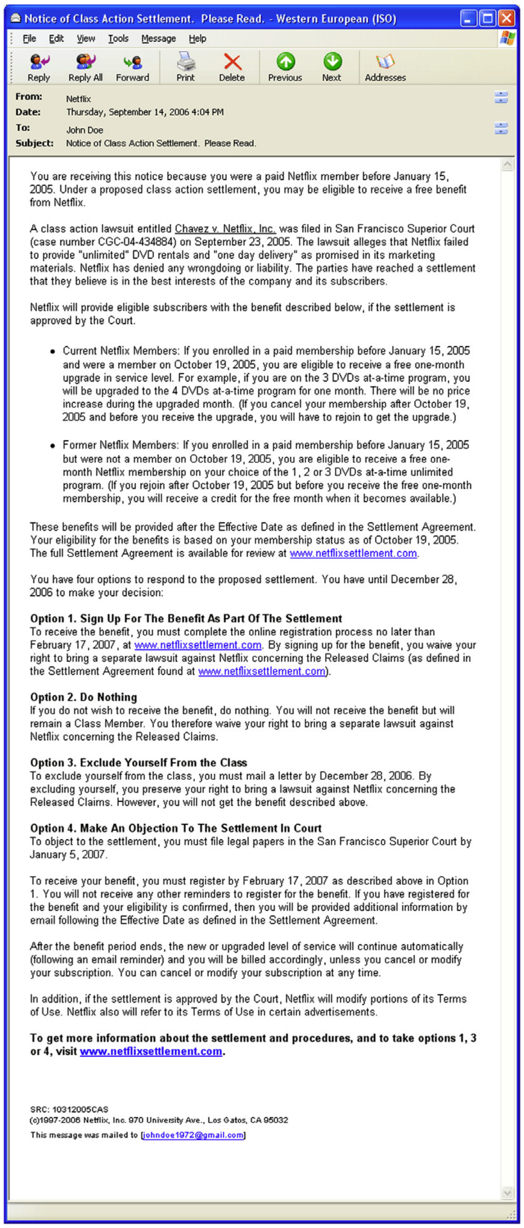
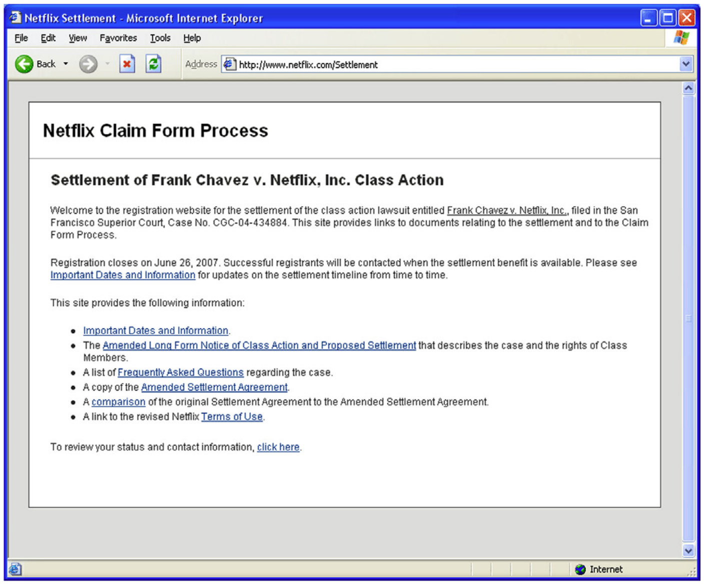
the page content. Though subjects gave a higher average rating to our modified Citibank cardmembers login page, the test showed that the two distributions were not significantly different ($p = 0{:}133$).

The last test pair was nearly significant ($p = 0{:}65$) but does not confirm that the two ratings come from different distributions. This pair compared the effects of a plausible parent company domain and subsidiary subdirectory, http://www.ebaygroup.com/paypal/, with the authentic URL that reverses their positions, http://www.paypal.com/ebay/. Although the ebaygroup.com domain is unbound, eBay has registered it. Nevertheless, this test shows a certain flexibility in user acceptance of domain alignment. No PayPal client has seen the PayPal page



(a)



(b)

FIGURE e49.13 (a) Low-profile class-action suit. (b) a lengthy notice that describes a class-action lawsuit against Netflix, a settlement to the lawsuit, and options for claiming benefits.

displayed under the http://www.ebaygroup.com/paypal/ address, yet their authenticity ratings are not significantly different. This result furthers our conviction that semantic alignment between content and URL is a principal factor in authenticity evaluations.

The last two Web stimuli sets are not twins; they are the Dell battery replacement page and the Netflix settlement page. Both pages are authentic, although the content of the Netflix page was altered to appear relevant at the time of testing. They received polar opposite ratings. The Dell battery page was statistically indistinguishable from the highest-rated page (the authentic PayPal site), and the Netflix page rated dead last—significantly lower than the second lowest rating ($p = 1{:}20\ \ 10^{-7}$). As mentioned before, the Dell battery program stimuli benefit from a high visibility news story. It's noteworthy that the URL in the Web page (authentic) is different from the URL in the email (phishing), which subjects saw first. Subjects did not penalize the Web page for this inconsistency. Subjects may have had difficulty constructing a phishing

TABLE e49.1 The Other Third Party Attack.

Stimulus Description	Mean	Diff.	χ^2	*p*
Chase card payment statement (legit)–plain layout	3.40	0.36	11.89	0.018

Dell battery replacement email (phishing)	3.61			
Dell battery replacement Web page (authentic)	3.54			

Note: The first section of the table reports on the differences between email messages; the next section reports on the Web pages; and the last section gives the average rating for the third-party attacks.

scenario based on the informational nature of the page; there is no request for personal information.

Similarly, the Netflix settlement page does not make any overtures for personal information. Even more surprising is that the URL http://www.netflix.com/settlement/ aligns well with the content. Subjects may have dismissed the page based on mistrust of the email stimulus, which they viewed prior to (several screenshots before) the Web stimulus. The Netflix page is notable for its brevity and unsophisticated layout. It is the only page

An Agenda for Action for Social Engineering Tactics

Our results forecast the following social engineering tactics: (Check All Tasks Completed):

_____**1.** Construct messages with weak narratives (bordering on innocuous) but use strong design elements (graphics, small-print footer, endorsement logos) and identifying information to improve authenticity impressions.

_____**2.** Use softer bait. Messages that do not encapsulate an imminent request for information, such as the Dell battery bait, rated highly in the test.

_____**3.** Use plausibly unfamiliar administration pages; for example, the Dell Battery Return Program Web site provides a service that is not typically seen, such as a login page (so visitor expectations are less concrete).

_____**4.** Leverage high-profile news to produce messages with credible and strong narratives. Personalization will be less important in these cases.

_____**5.** Align domain names with page content. Although subjects were turned off by semantic mismatches between domain names and content, they were insensitive to malformed links (http://www-wellsfargo.com).

without graphics or logos of any kind. There are no apparent links back to the primary Netflix page. With the exception of the blue underlined hyperlinks and gray margins, the page is black and white. We take from this rating that utilizing minimalist design is a poor strategy for unsolicited communications, even for important and serious matters such as law.

3. IMPLICATIONS FOR CRIMEWARE

The experiment focused on design features and their effect on people's ability to distinguish authentic email and Web sites from malicious forgeries. Although presented in the context of phishing, we do not measure how often subjects disclose passwords or other sensitive data; rather, we identify design principles that convey authenticity. Just as phishing bait promises resolution upon revealing information, social crimeware bait may promise resolution contingent upon installing browser extensions or accepting self-signed Java applets. Presenting a convincing false identity to the victim is essential in both contexts (see checklist, "An Agenda For Action For Social Engineering Tactics").

With respect to the final point, the "rock-phish" gang has proven that effective domain alignment can be achieved through deceptive subdomains,[14] the control of which is delegated to the domain owner rather than the registrar. The following URL, from a social engineering attack in the wild, illustrates this tactic:

www.paypal.com.cgi.bin.account.webscr.cmd.login.run.php.draciimasi.info/webscr.php?cmd = Login

The registered domain is draciimasi.info, but the owners have prepended it with a deep subdomain. Since subjects accepted the substitution of a dash for a dot in www-wellsfargo.com, they could easily accept a dot for a slash, as above. Moreover, the preponderance of subdirectory names such as cgi, bin, webscr, and the like further clouds the issue for the technically uninformed. This tactic may be particularly effective for download pages because they tend to be buried several directories deep; login pages, on the other hand, are frequently in the root of a domain.

Example: Vulnerability of Web-Based Update Mechanisms

Legitimate Web sites often make their services contingent upon changing settings, installing extensions, or accepting certificates. One important example is Microsoft's Windows Update Web site. It scans the client for installation detail through ActiveX extensions. When accessing the Web site through a professionally managed client at Indiana University, an update is not possible because the administrators have disabled the service. However, the Web site (see Figure e49.14) suggests workarounds involving settings changes.

None of these suggestions will enable remote update for this professionally managed computer, but subtle

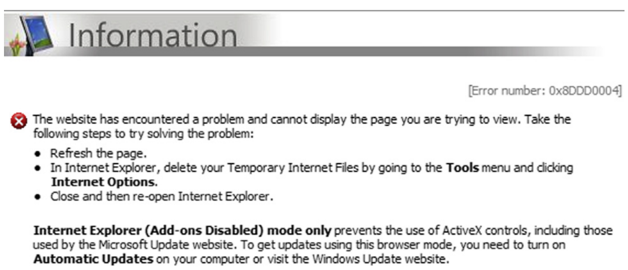

FIGURE e49.14 Suggested workarounds involving settings changes.

14. T. Moore and R. Clayton, "An empirical analysis of the current state of phishing attack and defense," The 2007 Workshop on the Economics of Information Security (WEIS 2007), 7–8 June 2007.

changes to the instructions could cause unsophisticated users to disengage important access controls. For example, the user could have been instructed to enter Addons Enabled mode. Subsequent installation of malicious add-ons will lead to a compromise. As long as the host's identity has been convincingly spoofed, users will be vulnerable to these kinds of attacks.

Example: The Unsubscribe Spam Attack

This attack leverages the first two tactics we discussed: weak narrative combined with strong design elements and softer bait. Some of the most highly rated email messages avoided hyperlinks in the main message text. The Chase account payment was completely devoid of hyperlinks and instead directed receivers to type www.chase.com into their address bar. Similarly, the PayPal message had no hyperlinks in its body, but it included a hyperlink in the footer to change preferences. The highly rated AT&T Universal card promotion also contains links in its small-print footer.

The attacker will send out promotional email that appears to come from the spoofed institution. The promotion would employ a weak narrative to shift user attention to a plethora of design features (graphical header, footer, small print, personalization, genuine but unlinked URLs in the body, and so on). The body will generate the perception of authenticity by referring the receivers to the phone number on back of her credit card or by requiring users to manually type in the promotional URL. Among the design features is a small-print footer with an unsubscribe hyperlink. This link will take users to a Web page that spreads crimeware simply by loading malicious JavaScript code, like a "drive-by pharming attack."

The bait message gets users to click on the link indirectly: annoyance with the volume of unsolicited messages. No suspicion is aroused through directions to change settings; the malware spreads on load.

The Strong Narrative Attack

The strong narrative attack engages the receiver with a plausible story, often bundling actions to well-known news stories. The Chase phishing message that promotes ePIN to incoming Bank One customers is such an example; it leverages in the news of the Bank One acquisition. The Dell battery program stimuli gain most of their credibility from the story's media coverage. The message maintains this credibility by deferring the request for personal information; standard attacks request an "account login" or "settings update" in the message body. This battery exchange program could have been turned into a "patch-now" attack by claiming that a firmware or operating system fix would prevent overheating.

Though scams that exploit strong narratives and current events are not new (many fraud cases capitalized on the September 11, 2001, and Hurricane Katrina tragedies[15,16]), our research suggests that they are less influenced by design features. This finding is supported by the persistence of the Nigerian code 419 advance fee scams.[17] One widespread form of this attack entices victims with a story of the death of a foreign dignitary and the need to move large amounts of money (allegedly to protect it from corrupt enemies); they offer the victim a cut for moving the money. After drawing the victim into this illusion, the scammers request advance fees to enable the transfer of money. These messages break many design rules that promote trust: They use poor spelling and grammar, email messages are often plaintext, return addresses are essentially anonymous using free email accounts. Yet these scams still account for large amounts of Internet fraud, exceeding $3 billion in losses according to some estimates.[18]

SUMMARY

This study tested the impact of several document features on user authenticity perceptions for both email messages and Web pages. The influence of these features was context dependent in email messages. We were surprised that this context was shaped more by a message's narrative strength, rather than its underlying authenticity. Third-party endorsements and glossy graphics proved to be effective authenticity stimulators when message content was short and unsurprising. The same document features failed to influence authenticity judgments in a significant way when applied to more involving messages. Most surprising was the huge increase in trust caused by a small-print footer in a message that already exhibited strong personalization with its greeting and presentation of a four-digit account number suffix.

The data suggest a link between narrative strength and susceptibility to trust-improving document features, but the experiment was not designed to test this hypothesis. Future work should characterize more precisely what kind

of messages can benefit from these features and what kind of messages are resistant to their sway.

Since spoofed Web page content need not differ from the authentic pages, we focused three Web page tests on the effects of semantic alignment between address bar URLs and page content. The first showed a clear statistical preference for a simulated Web page whose domain name matched its content rather than the genuine page whose domain was only weakly aligned with the same content. The second test, which created better alignment with a bogus domain name by altering company logos, failed to register a statistically significant change in authenticity ratings. The third test compared an authentic page (and URL) with an authentic version of the same page content paired with a well-aligned but bogus URL; the results which favored the genuine URL were just shy of statistical significance. In conclusion, we find that URL can change authenticity ratings.

This experiment also verified that it is possible to overuse well-intended notices about security and fraud. We observed a statistically significant negative effect of genuine, but heavy-handed, fraud warnings. Another test showed a statistically significant improvement in authenticity perception when using SSL and a third-party endorsement logo on a fraudulent Web page showing a suspiciously formed, but semantically well-aligned, domain name.

The experiment simulated two sequences (one email and one Web page) that appeared to be third parties charged with handling embarrassing incidents for their corporate clients. Though separated by many variables, one turned out to be among the most trusted stimuli in the test, whereas the other rank among the lowest. The poorly ranked one, though authentic, broke all the rules: poor publicity, long and rambling message, use of third-party domain names, and no graphics. The highly ranked one (whose bogus email message was concocted by the authors) benefited from a widely publicized recall message. The story overrode the message's poor personalization, illegitimate URL, and relatively simple layout.

These factors offer a glimpse into what kinds of social engineering tactics may be deployed in the future. We describe an unsubscribed attack which contains an innocuous message, many authenticity stimulating document features, and an unsubscribe link that leads to a noninteractively infectious Web site. Our tests with third-party administration suggest that organizations in the process of correcting an embarrassing incident are highly vulnerable to social engineering attacks. Finally, our findings suggest some common pitfalls for legitimate Internet communications to avoid: overuse of fraud warnings, utilization of poorly aligned domain names, failure to use HTTPS for rendering login pages, and long or rambling email messages.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Identity theft is commonly defined as unwanted appropriation of access credentials that allows creation and access of accounts and that allows the aggressor to pose as the victim.
2. True or False? Phishing is a form of Internet fraud that spoofs emails and Web pages to trick people into disclosing sensitive information.
3. True or False? Web sites, particularly the login and information collection pages associated with phishing scams, do present a story the way email messages do.
4. True or False? One way phishers align page content with URLs is by choosing an apt domain name; the other way is to change the page content.
5. True or False? Legitimate Web sites often make their services contingent upon changing settings, installing extensions, or accepting certificates.

Multiple Choice

1. An attacker will send out ___________ that appears to come from the spoofed institution.
   A. Privacy-enhancing technology
   B. Location technology
   C. Promotional email
   D. Executable policies
   E. Data controller
2. What message gets users to click on the link indirectly: annoyance with the volume of unsolicited messages?
   A. Policy enforcement
   B. Location technology
   C. Valid
   D. Environmental data
   E. Bait
3. What attack engages the receiver with a plausible story, often bundling actions to well-known news stories?
   A. Data minimization
   B. XACML
   C. Privacy risks
   D. Strong narrative
   E. Security

4. What is a type of identity theft that is perpetrated on the Internet and that typically relies on social engineering to obtain the access credentials of the victim?
   A. Privacy metrics
   B. Greedy strategy
   C. Sensitive information
   D. Phishing
   E. Taps
5. What is often defined as economically motivated malware?
   A. Irrelevant
   B. Sensor nodes
   C. Crimeware
   D. Disclose-to
   E. Server policy

Chapter 50

VoIP Security

Harsh Kupwade Patil
Southern Methodist University

Dan Wing
Cisco Systems

Thomas M. Chen
Swansea University

1. INTRODUCTION

H.323 and *Session Initiation Protocol* (SIP) are the two standardized protocols for the realization of VoIP.[1,2] The multimedia conference protocol H.323 of the International Telecommunication Union (ITU) consists of multiple separate protocols such as the H.245 for control signaling and H.225 for call signaling. H.323 is difficult to implement because of its complexity and the bulkiness that it introduces into the client application.[3] In contrast, SIP is simpler than H.323 and also leaner on the client-side application. SIP uses the human-readable protocol (ASCII) instead of H.323's binary signal coding.

VoIP Basics

SIP is the *Internet Engineering Task Force* (IETF) standard for multimedia communications in an IP network. It is an application layer control protocol used for creating, modifying, and terminating sessions between one or more SIP *user agents*. It was primarily designed to support user location discovery, user availability, user capabilities, and session setup and management.

In SIP, the end devices are called *user agents* (UAs), and they send SIP requests and SIP responses to establish media sessions, send and receive media, and send other SIP messages (to send short text messages to each other or subscribe to an event notification service). A UA can be a SIP phone or SIP client software running on a PC or PDA.

Typically, a collection of SIP user agents belongs to an administrative domain, which forms a SIP network. Each administrative domain has a SIP proxy, which is the point of contact for UAs within the domain and for UAs or SIP proxies outside the domain. All SIP signaling messages within a domain are routed through the domain's own SIP proxy. SIP routing is performed using *Uniform Resource Identifiers* (URIs) for addressing user agents. Two types of SIP URIs are supported: the SIP URI and the TEL URI. A SIP URI begins with the keyword *sip* or *sips*, where *sips* indicates that the SIP signaling must be sent over a secure channel, such as TLS.[4] The SIP URI is similar to an email address and contains a user's identifier and the domain at which the user can be found. For example, it could contain a username such as *sip:alice@example.com*, a global E.164 telephone number[5] such as *sip*:11-972-310-9882@*example.com;user = phone*, or an extension such as *sip*:1234@*example.com*. The TEL URI only contains an E.164 telephone number and does not contain a domain name, for example, *tel*: + 1.408.555.1234.

A SIP proxy server is an entity that receives SIP requests, performs various database lookups, and then forwards ("proxies") the request to the next-hop proxy server. In this way, SIP messages are routed to their ultimate destination. Each proxy may perform some specialized function, such as external database lookups, authorization checks, and so on. Because the media does

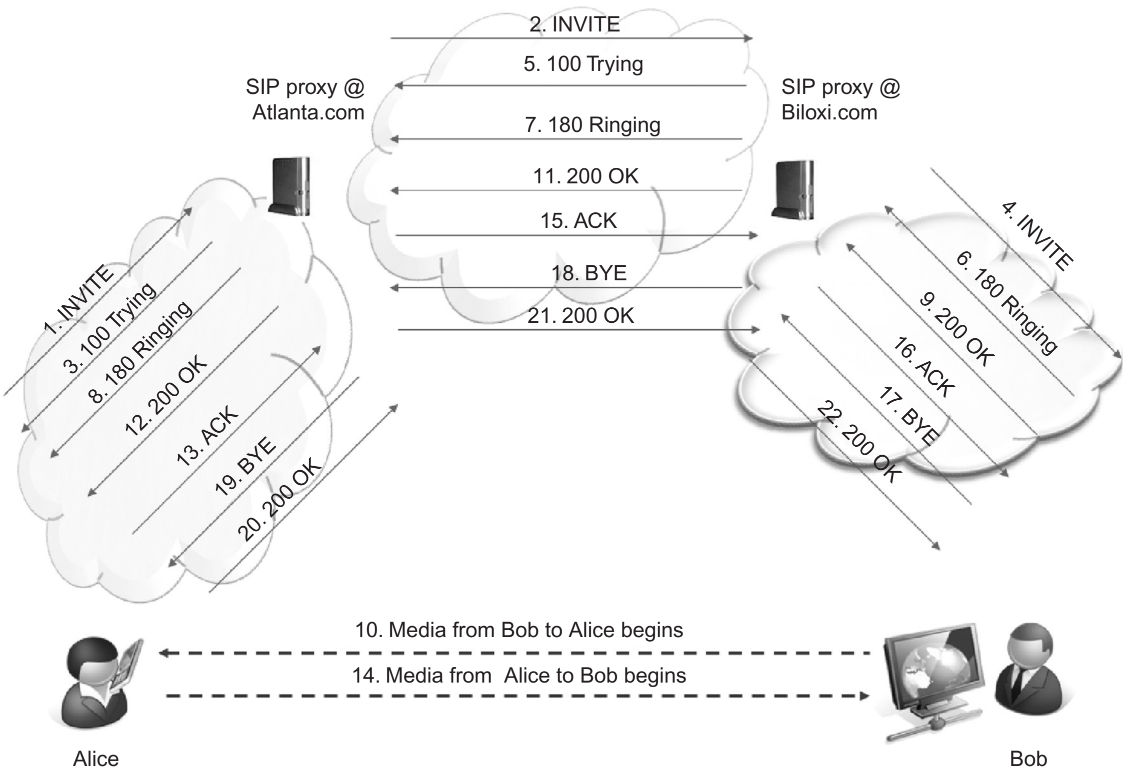

FIGURE 50.1 An example of a SIP session setup.

not flow through the SIP proxies—but rather only SIP signaling—SIP proxies are no longer needed after the call is established. In many SIP proxy designs, the proxies are stateless, which allows alternative intermediate proxies to resume processing for a failed (or overloaded) proxy. One type of SIP proxy called a *redirect server* receives a SIP request, performs a database query operation, and returns the lookup result to the requester (which is often another proxy). Another type of SIP proxy is a SIP *registrar server*, which receives and processes registration requests. Registration binds a SIP (or TEL) URI to the user's device, which is how SIP messages are routed to a user agent. Multiple UAs may register the same URI, which causes incoming SIP requests to be routed to all of those UAs, a process termed *forking*, which causes some interesting security concerns.

The typical SIP transactions can be broadly viewed by looking at the typical call flow mechanism in a SIP session setup, as shown in Figure 50.1. The term *SIP trapezoid* is often used to describe this message flow where the SIP signaling is sent to SIP proxies and the media is sent directly between the two UAs.

If Alice wants to initiate a session with Bob, she sends an initial SIP message *(INVITE)* to the local proxy for her domain (Atlanta.com). Her *INVITE* has Bob's URI (bob@biloxi.com) as the Request-URI, which is used to route the message. Upon receiving the initial message from Alice, her domain's proxy sends a provisional 100 *Trying* message to Alice, which indicates that the message was received without error from Alice. The Atlanta.com proxy looks at the *SIP Request-URI* in the message and decides to route the message to the Biloxi.com proxy. The Biloxi.com proxy receives the message and routes it to Bob. The Biloxi.com proxy delivers the *INVITE* message to Bob's SIP phone, to alert Bob of an incoming call. Bob's SIP phone initiates a provisional 180 *Ringing* message back to Alice, which is routed all the way back to Alice; this causes Alice's phone to generate a ringback tone, audible to Alice. When Bob answers his phone a 200 *OK* message is sent to his proxy, and Bob can start immediately sending media ("Hello?") to Alice. Meanwhile, Bob's 200 OK is routed from his proxy to Alice's proxy and finally to Alice's UA. Alice's UA responds with an *ACK* message to Bob and then Alice can begin sending media (audio and/or video) to Bob. Real-time media is almost exclusively sent using the Real-time Transport Protocol (RTP).[6] At this point the proxies are no longer involved in the call and hence the media will typically flow directly between Alice and Bob.

6. H. Schulzrinne, R. Frederick, and V. Jacobson, "RTP: A transport protocol for real-time applications," IETF RFC 1889, Jan. 1996.

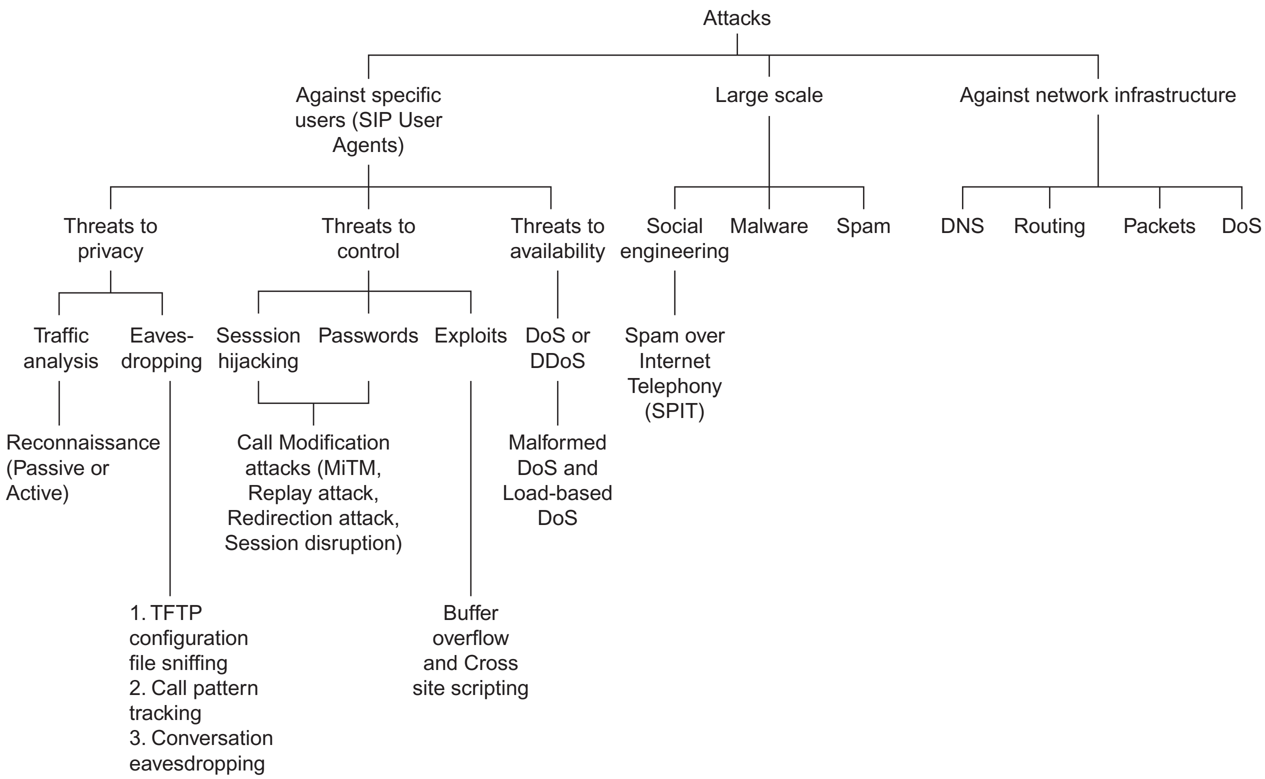

FIGURE 50.2 Taxonomy of threats.

That is, the media takes a different path through the network than the signaling. Finally, when either Alice or Bob want to end the session, they send a *BYE* message to their proxy, which is routed to the other party and is acknowledged.

One of the challenging tasks faced by the industry today is secure deployment of VoIP. During the initial design of SIP, the focus was more on providing new dynamic and powerful services along with simplicity rather than security. For this reason, a lot of effort is under way in the industry and among researchers to enhance SIP's security. The subsequent sections of this chapter deal with these issues.

2. OVERVIEW OF THREATS

Attacks can be broadly classified as attacks against specific users (SIP user agents), large scale (VoIP is part of the network) and against network infrastructure (SIP proxies or other network components and resources necessary for VoIP, such as routers, DNS servers, and bandwidth).[7] This chapter does not cover attacks against infrastructure; the interested reader is referred to the literature.[8] The subsequent parts of this chapter deal with the attacks targeted toward the specific host and issues related to social engineering. The taxonomy of attacks is shown in Figure 50.2.

Reconnaissance of VoIP Networks

Reconnaissance refers to intelligent gathering or probing to assess the vulnerabilities of a network, to successfully launch a later attack; it includes *footprinting* the target (also known as *profiling* or *information gathering*). The two forms of reconnaissance techniques are passive and active. Passive reconnaissance attacks include the collection of network information through indirect or direct methods but without probing the target; active reconnaissance attacks involve generating traffic with the intention of eliciting responses from the target. Passive reconnaissance techniques would involve searching for publicly available SIP URIs in databases provided by VoIP service providers or on Web pages, looking for publicly accessible SIP proxies or SIP UAs. Examples include *dig* and

7. T. Chen and C. Davis, "An overview of electronic attacks," in *Information Security and Ethics: Concepts, Methodologies, Tools and Applications*, H. Nemati (ed.), Idea Group Publishing, to appear 2008.

8. A. Chakrabarti and G. Manimaran, "Internet infrastructure security: a taxonomy," IEEE Network, Vol. 16, pp. 13–21, Dec. 2002.

nslookup. Although passive reconnaissance techniques can be effective, they are time intensive.

If an attacker can watch SIP signaling, the attacker can perform number harvesting. Here, an attacker passively monitors all incoming and outgoing calls to build a database of legitimate phone numbers or extensions within an organization. This type of database can be used in more advanced VoIP attacks such as signaling manipulation or Spam over Internet Telephony (SPIT) attacks.

Active reconnaissance uses technical tools to discover information on the hosts that are active on the target network. The drawback to active reconnaissance, however, is that it can be detected. The two most common active reconnaissance attacks are call walking attacks and port-scanning attacks.

Call walking is a type of reconnaissance probe in which a malicious user initiates sequential calls to a block of telephone numbers to identify what assets are available for further exploitation. This is a modern version of *war-dialing*, common in the 1980s to find modems on the Public Switched Telephone Network (PSTN). Performed during non-business hours, call walking can provide information useful for social engineering, such as voicemail announcements that disclose the called party's name.

SIP UAs and proxies listen on UDP/5060 and/or TCP/5060, so it can be effective to scan IP addresses looking for such listeners. Once the attacker has accumulated a list of active IP addresses, he can start to investigate each address further. The Nmap tool is a robust port scanner that is capable of performing a multitude of types of scans.[9]

In addition, honeypots and honeynets are becoming increasingly popular, as it would help detect, prevent or prepare to respond to attacks. A honeypot is a trap where vulnerabilities are deliberately introduced to lure attackers (hackers) and then analyze their activity (probing, security attack or compromise). While, a honeynet is a collection of honeypots. In the domain of VoIP, honeynets can be useful in preventing Spam over Internet Telephony (SPIT) and VoIP Phishing (Vishing).

Denial of Service

A denial-of-service (DoS) attack deprives a user or an organization of services or resources that are normally available. In SIP, DoS attacks can be classified as malformed request DoS and load-based DoS.

Malformed Request DoS

In this type of DoS attack, the attacker would craft a SIP request (or response) that exploits the vulnerability in a SIP proxy or SIP UA of the target, resulting in a partial or complete loss of function. For example, it has also been found that some user agents allow remote attackers to cause a denial of service ("486 Busy" responses or device reboot) via a sequence of SIP INVITE transactions in which the Request-URI lacks a username.[10] Attackers have also shown that the IP implementations of some hard phones are vulnerable to IP fragmentation attacks [CAN-2002-0880] and DHCP-based DoS attacks [CAN-2002-0835], demonstrating that normal infrastructure protection (such as firewalls) is valuable for VoIP equipment. DoS attacks can also be initiated against other network services such as DHCP and DNS, which serve VoIP devices.

Load-Based DoS

In this case, an attacker directs large volumes of traffic at a target (or set of targets) and attempts to exhaust resources such as the CPU processing time, network bandwidth, or memory. SIP proxies and session border controllers (SBCs) are primary targets for attackers because of their critical role of providing voice service and the complexity of the software running on them.

A common type of load-based attack is a flooding attack. In case of VoIP, we categorize flooding attacks into these types:

- Control packet floods
- Call data floods
- Distributed denial-of-service attack

Control Packet Floods

In this case, the attacker will flood SIP proxies with SIP packets, such as INVITE messages, bogus responses, or the like. The attacker might purposefully craft authenticated messages that fail authentication, to cause the victim to validate the message. The attacker might spoof the IP address of a legitimate sender so that rate limiting the attack also causes rate limiting of the legitimate user as well.

Call Data Floods

The attacker will flood the target with RTP packets, with or without first establishing a legitimate RTP session, in an attempt to exhaust the target's bandwidth or processing power, leading to degradation of VoIP quality for other users on the same network or just for the victim. Other common forms of load-based attacks that could affect the VoIP system are buffer overflow attacks, TCP SYN flood, UDP flood, fragmentation attacks, smurf attacks, and general overload attacks. Though VoIP equipment needs to

9. http://nmap.org/.

10. The common vulnerability and exposure list for SIP, http://cve.mitre.org/cgibin/cvekey.cgi?keyword = SIP.

protect itself from these attacks, these attacks are not specific to VoIP.

A SIP proxy can be overloaded with excessive legitimate traffic—the classic "Mother's Day" problem when the telephone system is most busy. Large-scale disasters (earthquakes) can also cause similar spikes, which are not attacks. Thus, even when not under attack, the system could be under high load. If the server or the end user is not fast enough to handle incoming loads, it will experience an outage or misbehave in such a way as to become ineffective at processing SIP messages. This type of attack is very difficult to detect because it would be difficult to sort the legitimate user from the illegitimate users who are performing the same type of attack.

Distributed Denial-of-Service Attack

Once an attacker has gained control of a large number of VoIP-capable hosts and formed a "zombies" network under the attacker's control, the attacker can launch interesting VoIP attacks, as illustrated in Figure 50.3. Each zombie can send up to thousands of messages to a single location, thereby resulting in a barrage of packets, which incapacitates the victim's computer due to resource exhaustion.

Loss of Privacy

The four major eavesdropping attacks are:

- Trivial File Transfer Protocol (TFTP) configuration file sniffing
- Traffic analysis
- Conversation eavesdropping

TFTP Configuration File Sniffing

Most IP phones rely on a TFTP server to download their configuration file after powering on. The configuration file can sometimes contain passwords that can be used to directly connect back to the phone and administer it or used to access other services (such as the company directory). An attacker who is sniffing the file when the phone downloads this configuration file can glean through these passwords and potentially reconfigure and control the IP phone. To thwart this attack vector, vendors variously encrypt the configuration file or use HTTPS and authentication.

Traffic Analysis

Traffic analysis involves determining who is talking to whom, which can be done even when the actual conversation is encrypted and can even be done (to a lesser degree) between organizations. Such information can be beneficial to law enforcement and for criminals committing corporate espionage and stock fraud.

Conversation Eavesdropping

An important threat for VoIP users is eavesdropping on a conversation. In addition to the obvious problem of confidential information being exchanged between people, eavesdropping is also useful for credit-card fraud and identity theft. This is because some phone calls—

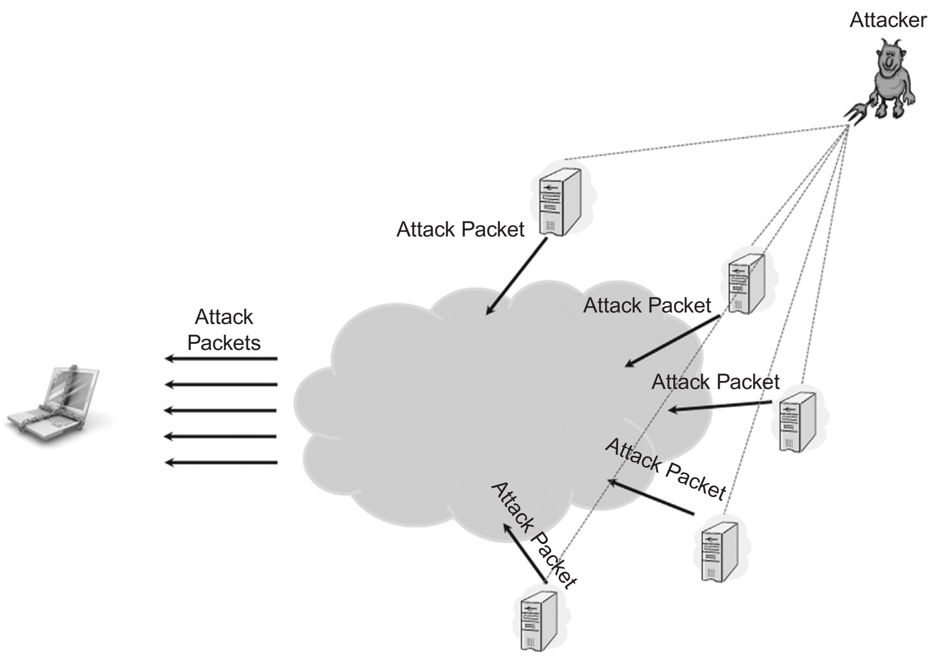

FIGURE 50.3 Distributed denial-of-service attack (DDoS).

especially to certain institutions—require users to enter credit-card numbers, PIN codes, or national identity numbers (Social Security numbers), which are sent as Dual-Tone Multi-frequency (DTMF) digits in RTP. An attacker can use tools like Wireshark, Cain & Abel, vomit (voice over misconfigured Internet telephones), VoIPong, and Oreka to capture RTP packets and extract the conversation or the DTMF digits.[11]

Man-in-the-Middle Attacks

The man-in-the-middle attack is a classic form of an attack where the attacker has managed to insert himself between the two hosts. It refers to an attacker who is able to read, and modify at will, messages between two parties without either party knowing that the link between them has been compromised. As such, the attacker has the ability to inspect or modify packets exchanged between two hosts or insert new packets or prevent packets from being sent to hosts. Any device that handles SIP messages as a normal course of its function could be a man in the middle: a compromised SIP proxy server or session border controller. If SIP messages are not authenticated, an attacker can also compromise a DNS server or use DNS poisoning techniques to cause SIP messages to be routed to a device under the attacker's control.

In a conventional enterprise network, VoIP phones are configured with different Virtual Local Area Network (VLAN) addresses as opposed to data devices. In such situations, the attacker would initially access the network by connecting his laptop to the existing data VLAN and then hop to the designated voice VLAN. This attack can be achieved in two ways: switch spoofing or double tagging. If a network switch is configured for autotrunking, the attacker converts it to a switch that needs to trunk. In the second method, the attacker sends data from one switch to another by sending frames with two 802.1Q headers (one for the victim's switch and the other for the attacking switch). The victim's switch accepts any incoming frames, while the target switch forwards the second frame (embedded with a false-tag) to the destination host based on the VLAN identifier present in the second 802.1q header. Once, inside the desired voice VLAN, the attacker could Address Resolution Protocol (ARP) poison the designated phones that would result in a Man-in-the-middle attack.

Replay Attacks

Replay attacks are often used to impersonate an authorized user. A replay attack is one in which an attacker captures a valid packet sent between the SIP UAs or proxies and resends it at a later time (perhaps a second later, perhaps days later). As an example with classic unauthenticated telnet, an attacker that captures a telnet username and password can replay that same username and password. In SIP, an attacker would capture and replay valid SIP requests. (Capturing and replaying SIP responses is usually not valuable, as SIP responses are discarded if their Call-Id does not match a currently outstanding request, which is one way SIP protects itself from replay attacks.)

If Real-time Transport Protocol (RTP) is used without authenticating Real-time Transport Control Protocol (RTCP) packets and without sampling synchronization source (SSRC), an attacker can inject RTCP packets into a multicast group, each with a different SSRC, and force the group size to grow exponentially. A variant on a replay attack is the cut-and-paste attack. In this scenario, an attacker copies part of a captured packet with a generated packet. For example, a security credential can be copied from one request to another, resulting in a successful authorization without the attacker even discovering the user's password.

Impersonation

Impersonation is described as a user or host pretending to be another user or host, especially one that the intended victim trusts. In case of a phishing attack, the attacker continues the deception to make the victim disclose his banking information, employee credentials, and other sensitive information. In SIP, the From header is displayed to the called party, so authentication and authorization of the values used in the From header are important to prevent impersonation. Unfortunately, call forwarding in SIP (called *retargeting*) makes simple validation of the From header impossible. For example, imagine Bob has forwarded his phone to Carol and they are in different administrative domains (Bob is at work, Carol is his wife at home). Then Alice calls Bob. When Alice's INVITE is routed to Bob's proxy, her INVITE will be retargeted to Carol's UA by rewriting the Request-URI to point to Carol's URI. Alice's original INVITE is then routed to Carol's UA. When it arrives at Carol's UA, the INVITE needs to indicate that the call is from Alice. The difficulty is that if Carol's SIP proxy were to have performed simplistic validation of the From in the INVITE when it arrived from Bob's SIP proxy, Carol's SIP proxy would have rejected it—because it contained Alice's From. However, such retargeting is a legitimate function of SIP networks.

Redirection Attack

If compromised by an attacker or via a SIP man-in-the-middle attack, the intermediate SIP proxies responsible

11. D. Endler and M. Collier, *Hacking VoIP Exposed: Voice over IP Security Secrets and Solutions*, McGraw-Hill, 2007.

for SIP message routing can falsify any response. In this section we describe how the attacker could use this ability to launch a redirection attack. If an attacker can fabricate a reply to a SIP INVITE, the media session can be established with the attacker rather than the intended party. In SIP, a proxy or UA can respond to an INVITE request with a 301 Moved Permanently or 302 Moved Temporarily Response. The 302 Response will also include an Expires header line that communicates how long the redirection should last. The attacker can respond with a redirection response, effectively denying service to the called party and possibly tricking the caller into communicating with, or through, a rogue UA.

Session Disruption

Session disruption describes any attack that degrades or disrupts an existing signaling or media session. For example, in the case of a SIP scenario, if an attacker is able to send failure messages such as BYE and inject them into the signaling path, he can cause the sessions to fail when there is no legitimate reason why they should not continue. For this to be successful, the attacker has to include the Call-Id of an active call in the BYE message. Alternatively, if an attacker introduces bogus packets into the media stream, he can disrupt packet sequence, impede media processing, and disrupt a session. Delay attacks are those in which an attacker can capture and resend RTP SSRC packets out of sequence to a VoIP endpoint and force the endpoint to waste its processing cycles in resequencing packets and degrade call quality. An attacker could also disrupt a Voice over Wireless Local Area Network (WLAN) service by disrupting IEEE 802.11 WLAN service using radio spectrum jamming or a Wi-Fi Protected Access (WPA) Message Integrity Check (MIC) attack. A wireless access point will disassociate stations when it receives two invalid frames within 60 seconds, causing loss of network connectivity for 60 seconds. A one-minute loss of service is hardly tolerable in a voice application.

Exploits

Cross-Site Scripting (XSS) attacks are possible with VoIP systems because call logs contain header fields, and administrators (and other privileged users) view those call logs. In this attack, specially crafted From: (or other) fields are sent by an attacker in a normal SIP message (such as an INVITE). Then later, when someone such as the administrator looks at the call logs using a Web browser, the specially crafted From; causes a XSS attack against the administrator's Web browser, which can then do malicious things with the administrator's privileges. This can be a damaging attack if the administrator has already logged into other systems (HR databases, the SIP call controller, the firewall) and her Web browser has a valid cookie (or active session in another window) for those other systems.

Social Engineering

SPIT (Spam over Internet Telephony) is classified as a social threat because the callee can treat the call as unsolicited, and the term *unsolicited* is strictly bound to be a user-specific preference, which makes it hard for the system to identify this kind of transaction. SPIT can be telemarketing calls used for guiding callees to a service deployed to sell products. IM spam and presence spam could also be launched via SIP messages. IM spam is very similar to email spam; presence spam is defined as a set of unsolicited presence requests for the presence package. A subtle variation of SPIT called *Vishing* (VoIP phishing) is an attack that aims to collect personal data by redirecting users toward an interactive voice responder that could collect personal information such as the PIN for a credit card. From a signaling point of view, unsolicited communication is technically a correct transaction.

Unfortunately, many of the mechanisms that are effective for email spam are ineffective with VoIP, for many reasons. First, the email with its entire contents arrives at a server before it is seen by the user. Such a mail server can therefore apply many filtering strategies, such as Bayesian filters, URL filters, and so on. In contrast, in VoIP, human voices are transmitted rather than text. To recognize voices and to determine whether the message is spam or not is still a very difficult task for the end system. A recipient of a call only learns about the subject of the message when he is actually listening to it. Moreover, even if the content is stored on a voice mailbox, it is still difficult for today's speech recognition technologies to understand the context of the message enough to decide whether it is spam or not.

One mechanism to fight automated systems that deliver spam is to challenge such suspected incoming calls with a Turing test. These methods include:

- *Voice menu*. Before a call is put through, a computer asks the caller to press certain key combinations, for example "Press #55."
- *Challenge models.* Before a call is put through, a computer asks the caller to solve a simple equation and to type in the answer—for example, "Divide 10 by 2."
- *Alternative number*. Under the main number a computer announces an alternative number. This number may even be changed permanently by a call management server. All these methods can even be enforced by enriching the audio signal with noise or music. This prevents SPIT bots from using speech recognition.

Such Turing tests are attractive, since it is often hard for computers to decode audio questions. However, these puzzles cannot be made too difficult, because human beings must always be able to solve them.

One of the solutions to the SPIT problem is the whitelist. In a whitelist, a user explicitly states which persons are allowed to contact him. A similar technique is also used in Skype; where Alice wants to call Bob, she first has to add Bob to her contact list and send a contact request to Bob. Only when Bob has accepted this request can Alice make calls to Bob.

In general, whitelists have an introduction problem, since it is not possible to receive calls by someone who is not already on the whitelist. Blacklists are the opposite of whitelists but have limited effectiveness at blocking spam because new identities (which are not on the blacklist) can be easily created by anyone, including spammers.

Authentication mechanisms can be used to provide strong authentication, which is necessary for strong whitelists and reputation systems, which form the basis of SPIT prevention. Strong authentication is generally Public Key Infrastructure (PKI) dependent. Proactive publishing of incorrect information, namely SIP addresses, is a possible way to fill up spammers' databases with existing contacts. Consent-based communication is the other solution. Address obfuscation could be an alternative wherein spam bots are unable to identify the SIP URIs.

3. SECURITY IN VOIP

Much existing VoIP equipment is dedicated to VoIP, which allows placing such equipment on a separate network. This is typically accomplished with a separate VLAN. Depending on the vendor of the equipment, this can be automated using CDP (Cisco Discovery Protocol), LLDP (Link Layer Discovery Protocol), or 802.1x, all of which will place equipment into a separate "voice VLAN" to assist with this separation. This provides a reasonable level of protection, especially within an enterprise where employees lack much incentive to interfere with the telephone system.

Preventative Measures

However, the use of VLANs is not an ideal solution because it does not work well with softphones that are not dedicated to VoIP, because placing those softphones onto the "voice VLAN" destroys the security and management advantage of the separate network. A separate VLAN can also create a false sense of security that only benign voice devices are connected to the VLAN. However, even though 802.1x provides the best security, it is still possible for an attacker to gain access to the voice VLAN (with a suitable hub between the phone and the switch). Mechanisms that provide less security, such as CDP or LLDP, can be circumvented by software on an infected computer. Some vendors' Ethernet switches can be configured to require clients to request inline Ethernet power before allowing clients to join certain VLANs (such as the voice VLAN), which provides protection from such infected computers. But, as mentioned previously, such protection of the voice VLAN prevents deployment of softphones, which is a significant reason that most companies are interested in deploying VoIP.

Eavesdropping

To counter the threat of eavesdropping, the media can be encrypted. The method to encrypt RTP traffic is Secure RTP (RFC3711), which does not encrypt the IP, UDP, or RTP headers but does encrypt the RTP payload (the "voice" itself). SRTP's advantage of leaving the RTP headers unencrypted is that header compression protocols (cRTP,[12] ROHC,[13]) and protocol analyzers (looking for RTP packet loss and (S)RTCP reports) can still function with SRTP-encrypted media.

The drawback of SRTP is that approximately 13 incompatible mechanisms exist to establish the SRTP keys. These mechanisms are at various stages of deployment, industry acceptance, and standardization. Thus, at this point in time it is unlikely that two SRTP-capable systems from different vendors will have a compatible SRTP keying mechanism. A brief overview of some of the more popular keying mechanisms is provided here.

One of the popular SRTP keying mechanisms, Security Descriptions, requires a secure SIP signaling channel (SIP over TLS) and discloses the SRTP key to each SIP proxy along the call setup path. This means that a passive attacker, able to observe the unencrypted SIP signaling and the encrypted SRTP, would be able to eavesdrop on a call. S/MIME is SIP's end-to-end security mechanism, which Security Descriptions could use to its benefit, but S/MIME has not been well deployed and, due to specific features of SIP (primarily forking and retargeting), it is unlikely that S/MIME will see deployment in the foreseeable future.

Multimedia Internet Keying (MIKEY) has approximately eight incompatible modes defined; these allow establishing SRTP keys.[14] Almost all these MIKEY modes are more secure than Security Descriptions

12. T. Koren, S. Casner, J. Geevarghese, B. Thompson, and P. Ruddy, "Enhanced compressed RTP (CRTP) for links with high delay," IETF RFC 3545, July 2003.
13. G. Pelletier and K. Sandlund, "Robust header compression version 2 (ROHCv2): Profiles for RTP, UDP, IP, ESP and UDP-Lite," IETF RFC 5225, April 2008.
14. S. Fries and D. Ignjatic, "On the applicability of various MIKEY modes and extensions," IETF draft, March 31, 2008.

because they do not carry the SRTP key directly in the SIP message but rather encrypt it with the remote party's private key or perform a Diffie-Hellman exchange. Thus, for most of the MIKEY modes, the attacker would need to actively participate in the MIKEY exchange and obtain the encrypted SRTP to listen to the media.

Zimmermann Real-time Transport Protocol (ZRTP)[15] is another SRTP key exchange mechanism, which uses a Diffie-Hellman exchange to establish the SRTP keys and detects an active attacker by having the users (or their computers) validate a short authentication string with each other. It affords useful security properties, including perfect forward secrecy and key continuity (which allows the users to verify authentication strings once, and never again), and the ability to work through session border controllers.

In 2006, the IETF decided to reduce the number of IETF standard key exchange mechanisms and chose DTLS-SRTP. DTLS-SRTP uses Datagram TLS (a mechanism to run TLS over a non-reliable protocol such as UDP) over the media path. To detect an active attacker, the TLS certificates exchanged over the media path must match the signed certificate fingerprints sent over the SIP signaling path. The certificate fingerprints are signed using SIP's identity mechanism.[16]

A drawback with SRTP is that it is imperative (for some keying mechanisms) or very helpful (with other keying mechanisms) for the SIP user agent to encrypt its SIP signaling traffic with its SIP proxy. The only standard for such encryption, today, is SIP-over-TLS which runs over TCP. To date, many vendors have avoided TCP on their SIP proxies because they have found SIP-over-TCP scales worse than SIP-over-UDP. It is anticipated that if this cannot be overcome we may see SIP-over-DTLS standardized. Another viable option, especially in some markets, is to use IPsec ESP to protect SIP.

Another drawback of SRTP is that diagnostic and troubleshooting equipment cannot listen to the media stream. This may seem obvious, but it can cause difficulties when technicians need to listen to and diagnose echo, gain, or other anomalies that cannot be diagnosed by examining SRTP headers (which are unencrypted) but can only be diagnosed by listening to the decrypted audio itself.

Identity

As described in the "Threats" section, it is important to have strong identity assurance. Today there are two mechanisms to provide for identity: P-Asserted-Identity,[17] which is used within a trust domain (within a company or between a service provider and its paying customers) and is simply a header inserted into a SIP request, and SIP Identity,[18] which is used between trust domains (between two companies) and creates a signature over some of the SIP headers and over the SIP body.

SIP Identity is useful when two organizations connect via SIP proxies, as was originally envisioned as the SIP architecture for intermediaries between two organizations—often a SIP service provider. Many of these service providers operate session border controllers (SBCs) rather than SIP proxies, for a variety of reasons. One of the drawbacks of SIP Identity is that an SBC, by its nature, will rewrite the SIP body (specifically the m = / c = lines), which destroys the original signature. Thus, an SBC would need to rewrite the From header and sign the new message with the SBC's own private key. This effectively creates hop-by-hop trust; each SBC that needs to rewrite the message in this way is also able to manipulate the SIP headers and SIP body in other ways that could be malicious or could allow the SBC to eavesdrop on a call. Alternative cryptographic identity mechanisms are being pursued, but it is not yet known whether this weakness can be resolved.

Traffic Analysis

The most useful protection from traffic analysis is to encrypt your SIP traffic. This would require the attacker to gain access to your SIP proxy (or its call logs) to determine who you called.

Additionally, your (S)RTP traffic itself could also provide useful traffic analysis information. For example, someone may learn valuable information just by noticing where (S)RTP traffic is being sent (the company's in-house lawyers are calling an acquisition target several times a day). Forcing traffic to be concentrated to a device can help prevent this sort of traffic analysis. In some network topologies this can be achieved using a NAT, and in all cases it can be achieved with an SBC.

Reactive

An intrusion prevention system (IPS) is a useful way to react to VoIP attacks against signaling or media. An IPS with generic rules and with VoIP-specific rules can detect an attack and block or rate-limit traffic from the offender.

15. P. Zimmermann, A. Johnston, and J. Callas, "ZRTP: Media path key agreement for secure RTP," IETF draft, July 9, 2007.

17. C. Jennings, J. Peterson and M. Watson, "Private extensions to the Session Initiation Protocol (SIP) for asserted identity within trusted networks," IETF RFC 3325, November 2002.
18. J. Peterson and C. Jennings, "Enhancements for authenticated identity management in the Session Initiation Protocol (SIP)," IETF RFC 4474, August 2006.

IPS

Because SIP is derived from, and related to, many well-deployed and well-understood protocols (HTTP), IDS/IPS vendors are able to create products to protect against SIP quite readily. Often an IDS/IPS function can be built into a SIP proxy, SBC, or firewall, reducing the need for a separate IDS/IPS appliance. An IDS/IPS is marginally effective for detecting media attacks, primarily to notice an excessive amount of bandwidth is being consumed and to throttle it or alarm the event.

A drawback of IPS is that it can cause false positives and deny service to a legitimate endpoint, thus causing a DoS in an attempt to prevent a DoS. An attacker, knowledgeable of the rules or behavior of an IPS, may also be able to spoof the identity of a victim (the victim's source IP address or SIP identity) and trigger the IPS/IDS into reacting to the attack. Thus, it is important to deny attackers that avenue by using standard best practices for IP address spoofing[19] and employing strong SIP identity. Using a separate network (VLAN) for VoIP traffic can help reduce the chance of false positives, as the IDS/IPS rules can be more finely tuned for that one application running on the voice VLAN.

Rate Limiting

When suffering from too many SIP requests due to an attack, the first thing to consider doing is simple rate limiting. This is often naïvely performed by simply rate limiting the traffic to the SIP proxy and allowing excess traffic to be dropped. Though this does effectively reduce the transactions per second the SIP proxy needs to perform, it interferes with processing of existing calls to a significant degree. For example, a normal call is established with an INVITE, which is reliably acknowledged when the call is established. If the simplistic rate limiting were to drop the acknowledgment message, the INVITE would be retransmitted, incurring additional processing while the system is under high load. A separate problem with rate limiting is that both attackers and legitimate users are subject to the rate limiting; it is more useful to discriminate the rate limiting to the users causing the high rate. This can be done by distributing the simple rate limiting toward the users rather than doing the simple rate limiting near the server.

On the server, a more intelligent rate limiting is useful. These are usually proprietary rate-limiting schemes, but they attempt to process existing calls before processing new calls. For example, such a scheme would allow processing the acknowledgment message for a previously processed INVITE, as described above; process the BYE associated with an active call, to free up resources; or process high-priority users' calls (the vice president's office is allowed to make calls, but the janitorial staff is blocked from making calls).

By pushing rate limiting toward users, effective use can be made of simple packet-based rate limiting. For example, even a very active call center phone does not need to send 100 Mb of SIP signaling traffic to its SIP proxy; even 1 Mb would be an excessive amount of traffic. By deploying simplistic, reasonable rate limiting very near the users, ideally at the Ethernet switch itself, bugs in the call processing application or malicious attacks by unauthorized software can be mitigated.

A similar situation occurs with the RTP media itself. Even high-definition video does not need to send or receive 100 Mb of traffic to another endpoint and can be rate-limited based on the applications running on the dedicated device. This sort of policing can be effective at the Ethernet switch itself, or in an IDS/IPS (watching for excessive bandwidth), a firewall, or SBC.

Challenging

A more sophisticated rate-limiting technique is to provide additional challenges to a high-volume user. This could be done when it is suspected that the user is sending spam or when the user has initiated too many calls in a certain time period. A simple mechanism is to complete the call with an interactive voice response system that requests the user to enter some digits ("Please enter 5, 1, 8 to complete your call"). Though this technique suffers from some problems (it does not work well for hearing-impaired users or if the caller does not understand the IVR's language), it is effective at reducing the calls per second from both internal and external callers.

4. FUTURE TRENDS

Certain SIP proxies have the ability to forward SIP requests to multiple user agents. These SIP requests can be sent in parallel, in series, or a combination of both series and parallel. Such proxies are called *forking proxies*.

Forking Problem in SIP

The forking proxy expects a response from all the user agents who received the received the request; the proxy forwards only the "best" final response back to the caller. This behavior causes a situation known as the

19. P. Ferguson and D. Senie, "Network ingress filtering: Defeating denial of service attacks which employ IP source address spoofing," IETF 2827, May 2000.

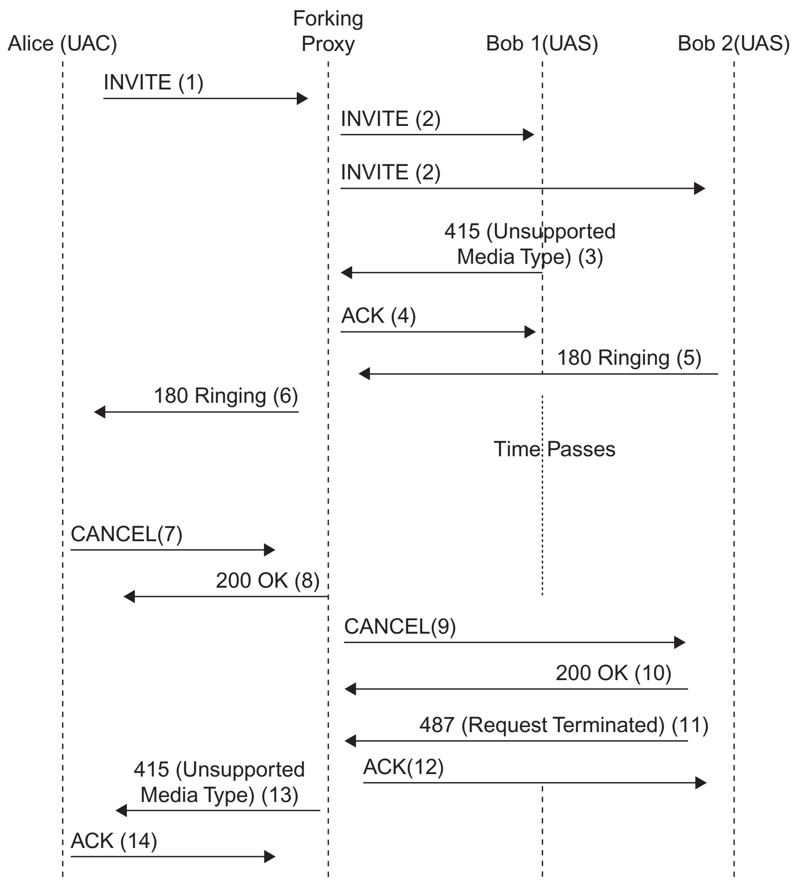

FIGURE 50.4 The heterogeneous error response forking problem.

heterogeneous error response forking problem [HERFP], which is illustrated in Figure 50.4.[20]

Alice initiates an INVITE request that includes a body format that is understood by UAS2 but not UAS1. For example, the UAC might have used a MIME type of multipart/mixed with a session description and an optional image or sound. As UAC1 does not support this MIME format, it returns a 415 (Unsupported Media Type) response. Unfortunately the proxy has to wait until all the branches generate the final response and then pick the "best" response, depending on the criteria mentioned in RFC 3261. In many cases the proxy has to wait a long enough time that the human operating the UAC abandons the call. The proxy informs the UAS2 that the call has been canceled, which is acknowledged by UAS2. It then returns the 415 (Unsupported Media Type) back to Alice, which could have been repaired by Alice by sending the appropriate session description.

Security in Peer-to-Peer SIP

Originally SIP was specified as a client/server protocol, but recent proposals suggest using SIP in a peer-to-peer setting.[21] One of the major reasons for using SIP in a peer-to-peer setting is its robustness, since there is no centralized control. As defined, "peer to peer (P2P) systems are distributed systems without any centralized control or hierarchical organization." This definition defines pure P2P systems. Even though many networks are considered P2P, they employ central authority or use supernodes. Early systems used flooding to route messages, which was found to be highly inefficient. To improve lookup time for a search request, structured overlay networks have been developed that provide load balancing and efficient routing of messages. They use distributed hash tables (DHTs) to provide efficient lookup.[22] Examples of

22. H. Balakrishnan, M. FransKaashoek, D. Karger, R. Morris, and I. Stoica, "Looking up data in P2P systems," *Communications of the ACM*, Vol. 46, No. 2, February 2003.

structured overlay networks are CAN, Chord, Pastry, and Tapestry.[23,24,25,26]

We focus on Chord Protocol because it is used as a prototype in most proposals for P2P-SIP. Chord has a ring-based topology in which each node stores at most log(N) entries in its finger table, which is like an application-level routing table, to point to other peers. Every node's IP address is mapped to an m bit chord identifier with a predefined hash function h. The same hash function h is also used to map any key of data onto a key ID that forms the distributed hash table. Every node maintains a finger table of log(N) = 6 entries, pointing to the next-hop node location at distance 2^{i-1} (for i = 1,2. . .m) from this node identifier. Each node in the ring is responsible for storing the content of all key IDs that are equal to the identifier of the node's predecessor in the Chord ring. In a Chord ring each node n stores the IP address of m successor nodes plus its predecessor in the ring. The m successor entries in the routing table point to nodes at increasing distance from n. Routing is done by forwarding messages to the largest node-ID in the routing table that precedes the key-ID until the direct successor of a node has a longer ID than the key ID.

Singh and Schulzrinne envision a hierarchical architecture in which multiple P2P networks are represented by a DNS domain. A global DHT is used for interdomain routing of messages.

Join/Leave Attack

Security of structured overlay networks is based on the assumption that joining nodes are assigned node-IDs at random due to random assignment of IP addresses. This could lead to a join/leave attack in which the malicious attacker would want to control O(log$N$) nodes out of N nodes as search is done on O(log$N$) nodes to find the desired key ID. With the adoption of IPv6, the join/leave attack can be more massive because the attacker will have more IP addresses. But even with IPv4, join/leave attacks are possible if the IP addresses are assigned dynamically. Node-ID assignment in Chord is inherently deterministic, thereby allowing the attacker to compute Node-IDs in advance where the attack could be launched by spoofing IP addresses. A probable solution would be to authenticate nodes before allowing them to join the overlay, which can involve authenticating the node before assigning the IP address.

Attacks on Overlay Routing

Any malicious node within the overlay can drop, alter, or wrongly forward a message it receives instead of routing it according to the overlay protocol. This can result in severe degradation of the overlay's availability. Therefore an adversary can perform one of the following:

Registration Attacks

One of the existing challenges to P2P-SIP registration is to provide confidentiality. This also includes message integrity to registration messages.

Man-in-the-middle Attacks

Let's consider the case where a node with ID 80 and a node with ID 109 conspire to form a man-in-the-middle attack, as shown in Figure 50.5. The honest node responsible for the key is node 180. Let's assume that a recursive approach is used for finding the desired key ID, wherein each routing node would send the request message to the appropriate node-ID until it reaches the node-ID responsible for the desired key-ID. The source node (node 30) will not have any control nor can it trace the request packet as it traverses through the Chord ring. Therefore node 32 will establish a dialog with node 119, and node 80 would impersonate node 32 and establish a dialog with node 108. This attack can be detected if an iterative routing mechanism is used wherein a source node checks whether the hash value is closer to the key-ID than the node-ID it received on the previous hop.[27] Therefore the source node (32) would get suspicious if node 80 redirected it directly to node 119, because it assumes that there exists a node with ID lower than Key ID 107.

Attacks on Bootstrapping Nodes

Any node wanting to join the overlay needs to be bootstrapped with a static node or cached node or discover the bootstrap node through broadcast mechanisms (SIP-

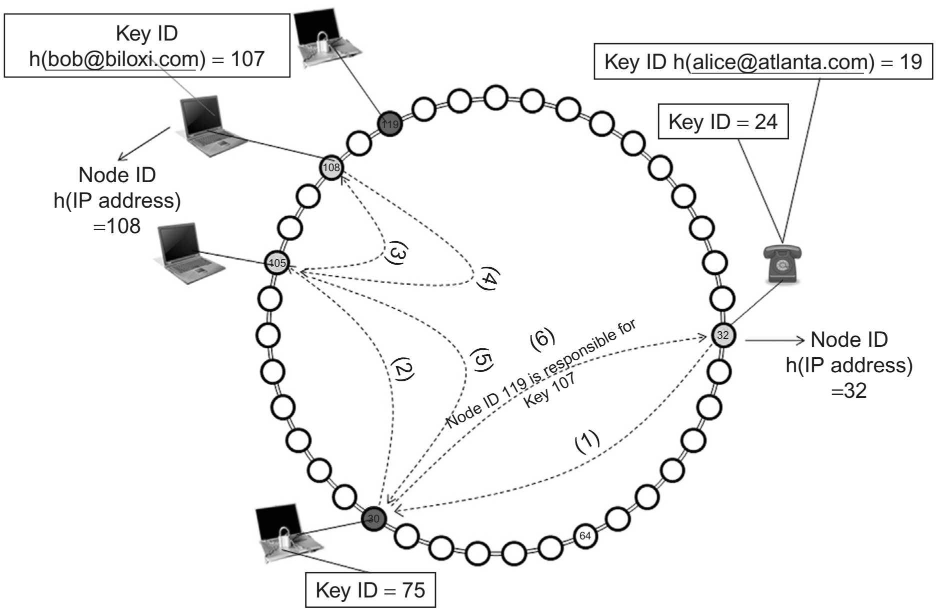

FIGURE 50.5 Man-in-the-middle attack.

multicast). In any case, if an adversary gains access to the bootstrap node, the joining node can easily be attacked. Securing the bootstrap node is still an open question.

Duplicate Identity Attacks

Preventing duplicate identities is one of the open problems whereby a hash of two IP addresses can lead to the same node-ID. The Singh and Schulzrinne approach reduces this problem somewhat by using a P2P network for each domain. Further, they suggest email-based authentication in which a joining node would receive a password via email and then use the password to authenticate itself to the network.

Free Riding

In a P2P system there is a risk of free riding in which nodes use services but fail to provide services to the network. Nodes use the overlay for registration and location service but drop other messages, which could eventually result in a reduction of the overlay's availability. The other major challenges that are presumably even harder to solve for P2P-SIP are as follows:

- Prioritizing signaling for emergency calls in an overlay network and ascertaining the physical location of users in real time may be very difficult.
- With the high dynamic nature of P2P systems, there is no predefined path for signaling traffic, and therefore it is impossible to implement a surveillance system for law enforcement agencies with P2P-SIP.

End-to-End Identity with SBCs

As discussed earlier,[28] End-to-End Identity with SBCs provides identity for SIP requests by signing certain SIP headers and the SIP body (which typically contains the Session Description Protocol (SDP)). This identity is destroyed if the SIP request travels through an SBC, because the SBC has to rewrite the SDP as part of the SBC's function (to force media to travel through the SBC). Today, nearly all companies that provide SIP trunking (Internet telephony service providers, ITSPs) utilize SBCs. In order to work with[29] those SBCs, one would have to validate incoming requests (which is new), modify the SDP and create a new identity (which they are doing today), and sign the new identity (which is new). As of this writing, it appears unlikely that ITSPs will have any reason to perform these new functions.

A related problem is that, even if we had end-to-end identity, it is impossible to determine whether a certain identity can rightfully claim a certain E.164 phone number in the From: header. Unlike domain names, which can have their ownership validated (the way email address validation is performed on myriad Web sites today), there is no de facto or written standard to determine whether an identity can rightfully claim to "own" a certain E.164.

An Agenda for Action for VoIP's Security Challenges

The following are some tips for ensuring a secure VoIP (Check All Tasks Completed):

_____**1.** Choose the VoIP protocols carefully.

_____**2.** Turn off unnecessary protocols.

_____**3.** Remember that each element in the VoIP infrastructure, accessible on the network like any computer, can be attacked.

_____**4.** Divide and conquer works well for VoIP networks.

_____**5.** Authenticate remote operations.

_____**6.** Separate VoIP servers and the internal network.

_____**7.** Make sure the VoIP security system can track the communications ports by reading inside the signaling packets to discover the ports selected and enable two endpoints to send media packets to each other.

_____**8.** Use Network Address Translation (NAT), even if in some cases, it poses a special problem for VoIP. NAT converts internal IP addresses into a single, globally unique IP address for routing across the Internet.

_____**9.** Use a security system that performs VoIP specific security checks.

It is anticipated that as SIP trunking becomes more commonplace, SIP spam will grow with it, and the growth of SIP spam will create the necessary impetus for the industry to solve these interrelated problems. Solving the end-to-end identity problem and the problem of attesting E.164 ownership would allow domains to immediately create meaningful whitelists. Over time these whitelists could be shared among SIP networks, end users, and others, eventually creating a reputation system. But as long as spammers are able to impersonate legitimate users, even creating a whitelist is fraught with the risk of a spammer guessing the contents of that whitelist (your bank, family member, or employer).

SIP Security Using Identity-Based Cryptography

Authentication in SIP has been a major concern and existing authentication schemes depend on PKI or shared secrets (passwords). Although PKI has existed for decades, the cost of maintaining the infrastructure has prevented enterprises from harnessing it to its fullest potential. In a PKI, the certificates contain a preset expiration date and if the validity date expires, or if the sender refreshes his keys, then the end user (callee) would have to obtain a new certificate from a public key repository. This retrieval process would involve the onerous task of certificate path construction and path validation processes. In such cases, Identity based cryptography can be extremely useful, as it eliminates the generation and maintenance of public key certificates. The basic idea behind an identity-based crypto-system is that end users can choose an arbitrary string (SIP URI) which represents their identity to compute their public key. As a result, it expunges the need for certificates from Certificate Authority (CA).[30] In addition, concatenation of user identity and Universally Unique Identifier (UUID) to generate a public key would greatly simplify the revocation process.

5. SUMMARY

With today's dedicated VoIP handsets, a separate voice VLAN provides a reasonable amount of security. Going forward, as non-dedicated devices become more commonplace, more rigorous security mechanisms will gain importance. This will begin with encrypted signaling and encrypted media and will evolve to include spam protection and enhancements to SIP to provide cryptographic assurance of SIP call and message routing.

As VoIP continues to grow, VoIP security solutions (see checklist, "An Agenda For Action For VoIP's Security Challenges") will have to consider consumer, enterprise and policy concerns. Some VoIP applications, commonly installed on PCs may be against corporate security policies (Skype). One of the biggest challenges with enabling encryption is with maintaining a public key infrastructure and the complexities involved in distributing public key certificates that would span to end users[31] and key synchronization between various devices belonging to the same end user agent.[32]

30. D. Berbecaru, A. Lioy, and M. Marian, "On the complexity of public key certificate validation," in *Proceedings of the 4th International Conference on Information Security, Lecture Notes in Computer Science*, Springer-Verlag, Vol. 2200, pp. 183–203, 2001.

31. C. Jennings and J. Fischl, "Certificate management service for the Session Initiation Protocol (SIP)," IETF draft April 5, 2008.

32. Z. Anwar, W. Yurcik, R. Johnson, M. Hafiz, and R. Campbell, "Multiple design patterns for voice over IP (VoIP) security," IPCCC 2006, pp. 485–492, April 10–12, 2006.

Using IPsec for VoIP tunneling across the Internet is another option; however, it is not without substantial overhead.[33] Therefore end-to-end mechanisms such as SRTP are specified for encrypting media and establishing session keys.

VoIP network designers should take extra care in designing intrusion detection systems that are able to identify never-before-seen activities and react according to the organization's policy. They should follow industry best practices for securing endpoint devices and servers. Current softphones and consumer-priced hardphones use the "haste-to-market" implementation approach and therefore become vulnerable to VoIP attacks. Therefore VoIP network administrators may evaluate VoIP endpoint technology, identify devices or software that will meet business needs and can be secured, and make these the corporate standards. With P2P-SIP, the lack of central authority makes authentication of users and nodes difficult. Providing central authority would dampen the spirit of P2P-SIP and would conflict the inherent features of distributed networks. A decentralized solution such as the reputation management system, where the trust values are assigned to nodes in the network based on prior behavior, would lead to a weak form of authentication because the credibility used to distribute trust values could vary in a decentralized system. Reputation management systems were more focused on file-sharing applications and have not yet been applied to P2P-SIP.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? H.323 and *Session Initiation Protocol* (SIP) are the two substandardized protocols for the realization of VoIP.
2. True or False? SIP is the *Internet Engineering Task Force* (IETF) substandard for multimedia communications in an IP network.
3. True or False? Attacks can be broadly classified as attacks against specific users (SIP user agents), large scale (VoIP is part of the network) and against network infrastructure (SIP proxies or other network components and resources necessary for VoIP, such as routers, DNS servers, and bandwidth).
4. True or False? *Reconnaissance* refers to intelligent gathering or probing to assess the vulnerabilities of a network, to successfully launch a later attack; it includes *footprinting* the target (also known as *profiling* or *information gathering*).
5. True or False? A denial-of-service (DoS) attack deprives a user or an organization of services or resources that are not normally available.

Multiple Choice

1. In what type of DoS attack, would the attacker craft a SIP request (or response) that exploits the vulnerability in a SIP proxy or SIP UA of the target, resulting in a partial or complete loss of function?

A. Privacy-enhancing technology
B. Location technology
C. Promotional email
D. Malformed request DoS
E. Data controller

2. In what case, would an attacker direct large volumes of traffic at a target (or set of targets) and attempt to exhaust resources such as the CPU processing time, network bandwidth, or memory?

A. Policy enforcement
B. Location technology
C. Valid
D. Load-Based DoS
E. Bait

3. In what case, would the attacker flood SIP proxies with SIP packets, such as INVITE messages, bogus responses, or the like?

A. Data minimization
B. XACML
C. Control packet floods
D. Strong narrative
E. Security

4. What is it called when the attacker floods the target with RTP packets, with or without first establishing a legitimate RTP session, in an attempt to exhaust the target's bandwidth or processing power, leading to degradation of VoIP quality for other users on the same network or just for the victim?

A. Call data floods
B. Greedy strategy
C. Sensitive information
D. Phishing
E. Taps

5. Most IP phones rely on a TFTP server to download their __________ after powering on?

A. Irrelevant
B. Sensor nodes
C. Crimeware
D. Configuration file
E. Server policy

EXERCISE

Problem

What are some of the disadvantages of VOIP?

Hands-On Projects

Project

Can one use their existing network equipment (routers, hubs, etc.) for a VOIP network?

Case Projects

Problem

What is a VOIP "softphone?"

Optional Team Case Project

Problem

Will a VOIP system continue to function during a power failure or cable outage?

Chapter e51

SAN Security

John McGowan
EMC Corporation

Jeffrey Bardin
Independent consultant

John McDonald
EMC Corporation

As with any IT subsystem, implementing the appropriate level of security for storage area networks (SANs) depends on many factors. The resources expended on protecting the SAN should reflect the value of the information stored on the SAN using a risk-based approach. A full assessment and classification of the data including threats, vulnerabilities, existing controls, and potential impact should the loss, disclosure, modification, interruption, and/or destruction of the data occur should be performed prior to configuration of the SAN. Anytime you consider security prior to actual build-out of a system or device, your expenditures are lower than attempting to bolt on the security after the fact. There are a number of inexpensive steps that can be taken to ensure that security is appropriate for the classification of data stored in the SAN.

As the use of SANs increases, the amount of data being stored increases exponentially, making the SAN a target for hackers, criminals, and disgruntled employees. To effectively protect a SAN, it is important to understand what actions increase security and what impact these actions have on the performance and usability of the environment. Ensuring a balance among protection capability, cost, performance, and operational considerations must be at the top of your list when applying controls to your SAN environment.

One thing to consider is that the most probable avenue of attack in a SAN is through the hosts connected to the SAN. There are potentially thousands of host, application, and operating system-specific security considerations that are beyond the scope of this chapter but should be followed as your systems and application administrators properly configure their owned devices.

1. ORGANIZATIONAL STRUCTURE

Every company has its own organizational structures and security requirements. These are typically driven by the type of business, types of regulations and statutes that focus corporate compliance, and the type of data stored in the SAN. All factors should be evaluated when developing a security policy that is appropriate for your environment. It is wise to incorporate existing security policies such as acceptable use policies (AUPs), data classification, and intellectual property policies along playbooks or standard operating procedures (SOPs) describing how the data is stored and managed.

As with best practice, implementation can lead to tradeoffs. Making a SAN more secure may result in additional management overhead or a reduction in ease-of-use capabilities or the introduction of ease-of-use capabilities that reduce the overall SAN security posture. The use of encryption could create an unacceptable performance hit if not applied properly. You may even find that SAN security best practices conflict with other IT policies. In some instances, functions required to implement a recommendation may not be available on a certain SAN. Other compensating controls need to be considered such as a process, policy, or triggered script that assists in implementing the control. Your implementation of security controls should be based on risk as defined in an assessment process during SAN deployment.

AAA

Authentication, authorization, and accounting (AAA) is a term for a framework for intelligently controlling access

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00051-9

to computer resources, enforcing policies, auditing usage, and providing the information necessary to bill for services. These combined processes are important for effective network management and security.

Authentication provides a way of identifying a user, typically by having the user enter a valid username and password before granting access. The process of authentication is based on each user having a unique set of criteria for gaining access. The AAA server compares the user's credentials with credentials stored in a database. If the credentials match, the user is granted access to the resource.

Authorization is the process of enforcing policies: determining what types or qualities of activities, resources, or services a user is permitted. For example, after logging into a system, the user may try to issue commands. The authorization process determines whether the user has the authority to issue such commands. Once you have authenticated a user, she may be authorized for multiple types of access or activity.

The final process in the AAA framework is accounting, which measures the resources a user consumes during access. This can include the amount of system time or the amount of data a user has sent and/or received during a session. Accounting is accomplished by logging session statistics and usage information and is used for authorization control, billing, trend analysis, resource utilization, and capacity planning activities.

Authentication, authorization, and accounting services are often provided by a dedicated AAA server – a program that performs these functions. A common standard by which network access servers interface with the AAA server is the Remote Authentication Dial-In User Service (RADIUS).

Assessment and Design

The first step in developing adequate datacenter controls is to know what the controls need to address—for example, the vulnerabilities that can be exploited. Some threats may seem very difficult, and hence unlikely to be exploited, but it is an essential piece of the process to understand them so that you can demonstrate that they are either mitigated or that it is not commercially reasonable to fix the problem. This step is essential since it is not usually the vulnerabilities that you already know about that will be exploited. Once you have identified the gaps in the datacenter, you can communicate the vulnerabilities to your data by implementing a comprehensive SAN security program. The first step is to develop a storage security standard that outlines the architecture, workflow process, and technologies to leverage when deploying enterprisewide storage networks. Today SAN security solutions are available to meet some needs of every individual topology, incorporating a wide variety of vendor products and architectural needs. It is essential that corporations aggressively take on the challenge of integrating these new security features and technologies to interoperate with existing security technologies while complying with and redefining existing standards, policies, and processes. The remainder of this section details the tasks within the planning and design phase. Included in this section are architecture planning and design details, considerations for design, best practices, and notes on data collection and documentation.

Review Topology and Architecture Options

Fabric security augments overall application security. It is not sufficient on its own; host and disk security are also required. You should consider each portion of the customer's SAN when determining the correct security configuration. Review the current security infrastructure and discuss present and future needs. Listed here are the most common discussion segments:

- *SAN management access.* Secure access to management services.
- *Fabric access.* Secure device access to fabric service.
- *Target access.* Secure access to targets and Logical Unit Numbers (LUNs).
- *SAN protocol.* Secure switch-to-switch communication protocols.
- *IP storage access.* Secure Fibre Channel over TCP/IP (FCIP) and Internet Small Computer System Interface (iSCSI) services.
- *Data integrity and secrecy.* Encryption of data both in transit and at rest.

Additional subjects to include in a networked storage strategy involve:

- Securing storage networking ports and devices
- Securing transmission and ISL interfaces
- Securing management tools and interfaces (Simple Network Management Protocol (SNMP), Telnet, IP interfaces)
- Securing storage resources and volumes
- Disabling SNMP management interfaces not used or needed
- Restricting use and access to Telnet and FTP for components

There are a several major areas of focus for securing storage networks. These include securing the fabric and its access, securing the data and where it is stored, securing the components, securing the transports, and securing the management tools and interfaces. This part of the chapter describes the following components:

- Protection rings (see sidebar, "Security and Protection")
- Restricting access to storage

- Access control lists (ACLs) and policies
- Port blocks and port prohibits
- Zoning and isolating resources
- File system permissions for Network-attached Storage (NAS) file access using Network File System (NFS), and Common Internet File System (CIFS)
- Operating system access control and management interfaces
- Control and monitor root and other supervisory access
- Physical and logical security and protection
- Virus protection and detection on management servers and PC

Restricting Access to Storage

Securing a storage network involves making sure that you protect the SAN itself as well as the storage. LUN mapping works by creating an access table on the storage device or host servers (persistent binding) that determines what servers, using World Wide Node Names (WWNN) or World Wide Port Names (WWPN), can access (read, read/write, etc.) a specific volume or LUN. Servers that do not have access to the specific LUN receive an I/O reject error or may not see the storage at all. Storage-based security is the last line of defense when it comes to controlling access to a storage resource LUN.

Device masking hides the existence of a storage device from all but a desired set of host connections. Because Fibre Channel fabrics support zoning based on individual devices (WWN Zoning) it is possible to perform device masking in the fabric [1].

2. ACCESS CONTROL LISTS (ACL) AND POLICIES

Authentication involves verifying the identity of people and devices that are attempting to gain authorization to storage network resources. Authentication involves use of a server such as a remote access dial-up server (RADIUS) commonly used in network environments to verify identity credentials. Access control lists implement authorization to determine who and what can have access to storage network resources. When looking at controlling access and isolating traffic within a single switch or director as well as in a single fabric of two or more switches all connected together, use the following techniques:

- Fabric, switch, and port binding with policies and ACLs
- Fabric and device zoning to control access
- Networking segmentation (traffic isolation)
- Port isolation (port blocks, prohibits, port isolation, and disablement)
- Partitioning and segmentation (logical domains, Virtual Storage Area Network (VSAN), Logical Storage Area Network (LSAN), virtual switches)

Security and Protection

Establish an overall security perimeter that is both physical and logical to restrict access to components and applications. Physical security includes placing equipment in locked cabinets and facilities that have access monitoring capabilities. Logical security involves securing those applications, servers, and other interfaces, including management consoles and maintenance ports, from unauthorized access. Also, consider who has access to backup and removable media and where the company stores them as part of an overall security perimeter and defense.

Secure your networks, including Local Area Networks (LANs), Metropolitan Area Networks (MANs), and Wide Area Networks (WANs), with various subnets and segments including Internet, intranet, and extranets with firewalls and DMZ access where applicable.

Secure your servers so that if someone attempts to access them using other applications, using public or private networks, or simply by walking up to a workstation or console, the servers are protected. Server protection is important; it is one of the most common points that an attacker will target. Make sure that the server has adequate protection on usernames, passwords, files, and application access permissions.

Control and monitor who has access to root and other supervisory modes of access, as well as who can install and configure software.

Protect your storage network interfaces including Fibre Channel, Ethernet for iSCSI, and NAS as well as management ports, interfaces, and tools. Tools including zoning, access control lists, binding, segmentation, authorizing, and authentication should be deployed within the storage network.

Protect your storage subsystems using zoning and LUN/volume mapping and masking. Your last line of defense should be the storage system itself, so make sure it is adequately protected.

Protect wide area interfaces when using Internet File Channel Protocol (iFCP), Fibre Channel over Internet Protocol (FCIP), Internet Small Computer System Interface (iSCSI), Synchronous Optical Networking/Synchrous Digital Hierarchy (SONET/SDH), Asynchrous Transfer Mode (ATM), and other means for moving data between locations. Set up VPNs to help guard data while it's in transit, along with compression and encryption. Maintain access control and audit trails of the management interface tools, and make sure that you change their passwords.

Data Integrity Field (DIF)

DIF provides a standard data-checking mechanism to monitor the integrity of data. DIF sends a block of information with integrity checks to an HBA. The HBA validates the data and sends the data block with its integrity check across the Fibre Channel fabric to the storage array. The storage array in turn validates the metadata and writes the data to Redundant Array of Independent Disks (RAID) memory. The array then sends the block of data to the disk, which validates the information before writing it to disk. DIF pinpoints where in the process of writing data to disk that the corruption occurred.

Diffie-Hellman: Challenge Handshake Authentication Protocol (DH-CHAP)

DH-CHAP is a forthcoming Internet Standard for the authentication of devices connecting to a Fibre Channel switch. DH-CHAP is a secure key-exchange authentication protocol that supports both switch-to-switch and host-to-switch authentication. DH-CHAP supports MD-5 and SHA-1 algorithm-based authentication.

Fibre-Channel Security Protocol (FC-SP)

FC-SP is a security framework that includes protocols to enhance Fibre Channel security in several areas, including authentication of Fibre Channel devices, cryptographically secure key exchange, and cryptographically secure communication between Fibre Channel devices. FC-SP is focused on protecting data in transit throughout the Fibre Channel network. FC-SP does not address the security of data which is stored on the Fibre Channel network.

Fibre-Channel Authentication Protocol (FCAP) FCAP is an optional authentication mechanism employed between any two devices. This would also include entities on a Fibre Channel network using certificates or optional keys.

Fibre-Channel Password Authentication Protocol (FCPAP) FCPAP is an optional password based authentication and key exchange protocol that is utilized in Fibre Channel networks. FCPAP is used to mutually authenticate Fibre Channel ports to each other.

Switch Link Authentication Protocol (SLAP)

SLAP is an authentication method for Fibre Channel switches that utilizes digital certificates to authenticate switch ports. SLAP was designed to prevent the unauthorized addition of switches into a Fibre Channel network.

Port Blocks and Port Prohibits

You can use zoning to isolate ports—for example, Fiber Connectivity (FICON) ports from open systems ports, and traffic. Other capabilities that exist on switches and directors that support Enterprise Systems Connection (ESCON) or FICON are port blocks and port prohibits. Port blocks and port prohibits are another approach independent of the upper-layer fabric and name server for protecting ESCON and FICON ports. Unlike fabric zoning that can span multiple switches and directors in a fabric, port blocks and prohibits are specific to an individual director.

Zoning and Isolating Resources

While a Fibre Channel-based storage network can theoretically have approximately 16 million addresses for servers, devices, and switches, the reality is a bit lower. Zones can be unique with devices isolated from each, or they can overlap with devices existing in different overlapping zones. You can accomplish port and fabric security using zoning combinations, including WWNN Soft zoning, WWPN Soft zoning as part of the T11 FC-SW-2 standard, along with hardware enforced port zoning.

3. PHYSICAL ACCESS

Physical access is arguably one of the most critical aspects of Fibre Channel SAN security. The Fibre Channel protocol is not designed to be routed (although SANs can be bridged), which means that what happens in the SAN should stay in the SAN. By implementing the rest of the best practices discussed in this chapter, strong physical access controls can almost ensure that any attempts to access the SAN from the outside will be thwarted, since an attacker would need to physically connect a fiber optic cable to a switch or array to gain access.

Physical controls should also include clear labeling for all cables and components. In performing a physical audit of the infrastructure, clear and accurate labeling will ensure that any changes are immediately detectable.

Controlling physical access to any storage medium is also critical. This applies not only to the disk drives in a SAN storage system but to any copies of the data, such as backup tapes. The best security management system can be easily defeated if an attacker can walk into a lightly controlled office area and walk out with backup tapes that were stored there.

4. CHANGE MANAGEMENT

A documented and enforced process should be in place for any actions that may change the configuration of any component connected to the SAN. Changes should be

reviewed beforehand to ensure that they will not compromise security, and any unapproved changes uncovered during a regular audit (discussed shortly) should be thoroughly investigated.

5. PASSWORD POLICIES

Normal password-related best practices, such as regular changing of passwords and the use of hard-to-guess passwords, should be implemented for all components on the SAN. This includes the storage systems, switches and hubs, hosts, and so on.

The generally accepted best practice for the industry is that passwords should be changed every three to six months, and passwords should be a minimum of eight characters long and include at least one number or symbol. However, customers should follow the policies that have been established to address their particular business requirements.

6. DEFENSE IN DEPTH

No single method of protecting a SAN can be considered adequate in the light of constantly evolving threats. The best possible approach is to implement a policy of layers of protection for every aspect of the environment, which forces an attacker to defeat multiple mechanisms to achieve their goal, increasing the probability of an attack being detected and defeated. The LAN that interconnects the SAN component's management interfaces, which is the most likely avenue of attack, should be protected by multiple layers of security measures, such as firewalls, security monitoring tools, and so forth. The first phase of many attempts to attack the SAN will usually come through these LAN (Ethernet) management connections.

7. VENDOR SECURITY REVIEW

In considering new hardware and software that will be installed in or interact with the SAN, a security review should be performed with customer security personnel, customer technical/administrative personnel, and vendor technical personnel to gain a complete understanding of the security capabilities of the product and how they can be integrated into the existing security framework.

Failure to implement any of these basic security practices can increase the possibility that a SAN may come under attack and that any such an attack may succeed in impacting the ability of the SAN to perform its functions. For additional information on IT security best practices, refer to the SANS Institute's Resources Web site (www.sans.org/resources/) and to the SAN Security site (www.sansecurity.com).

8. DATA CLASSIFICATION

To develop and implement security policies and tools that effectively protect the data in a SAN at an appropriate level, it is important to understand the value of the data to the organization. Though implementing a one-size-fits-all approach to protecting all the data can simplify security management, such an approach may impose excessive costs for certain types of data while leaving other data underprotected. For example, encrypting data on the host can provide a significant level of protection; however, such encryption can impose significant overhead on the host processing, reducing performance for the entire environment.

A review of all data on the SAN should be performed and appropriate classifications assigned based on business requirements. These classifications should be assigned appropriate protection requirements.

9. SECURITY MANAGEMENT

When any new SAN component (such as a storage array, switch, or host) is installed, it usually contains at least one factory configured access method (such as a default username/password). It is imperative that any such access method be immediately reconfigured to conform to the security policies that have been set up for the rest of the environment. Strong passwords should be utilized (as discussed shortly) and, if possible, the account name should be changed.

Security Setup

More complex components, such as the hosts and storage systems, provide even more sophisticated security mechanisms, such as support for access domains, which allow them to be integrated into a broader security infrastructure. The mechanism should be configured according to established security policies immediately on installation.

Unused Capabilities

Most SAN hardware provides multiple methods of access and monitoring, such as a Web-based interface, a telnet command-line interface, and an SNMP interface. Many also provide some method for uploading new versions of firmware, such as FTP or Trivial File Transfer Protocol (TFTP). Any interface capabilities that will not be utilized on a regular basis should be explicitly disabled on every SAN device. Update interfaces such as FTP should only be enabled while an update is being performed and should be immediately disabled when done, to prevent them from being exploited during attacks.

On SAN switches any ports that will not be used in the configuration should also be explicitly disabled to prevent them from being utilized if an attacker does manage to gain physical access to the SAN.

10. AUDITING

Virtually every component in a SAN provides some form of capability to log changes when they occur. For example, some storage systems make a log entry when a new LUN is created; most Fibre Channel switches make log entries when zoning is changed. Regular audits should be performed to ensure that the current configuration of the SAN and all its components agree with the currently documented configuration, including any changes made through the change management system.

Automated tools and scripts can be used to implement an effective auditing process. Most SAN components provide the capability to download a detailed text listing that shows the current configuration. By performing this task on a regular basis and comparing the results to established baseline configurations, changes can be quickly detected and, if necessary, investigated.

Updates

All patches and software/firmware updates to any SAN components should be reviewed in a timely manner to determine whether they may have an impact on security. If a particular update includes changes to address known security vulnerabilities, it should be applied as quickly as possible.

Monitoring

It is important to continuously monitor an infrastructure to detect and prevent attacks. For example, a brute-force password attack that generates an abnormally high amount of TCP/IP network traffic to a SAN switch can be easily detected and stopped using standard network monitoring tools before any impact occurs.

Monitoring can also detect changes to the SAN configuration that may indicate an attack is underway. For example, if an attacker attempts to "spoof" the world wide name (WWN) of another server to gain access to its storage, most switches will detect the existence of a duplicate WWN and generate error messages.

Security Maintenance

The security configuration of the SAN should be updated in a timely manner to reflect changes in the environment—for example, the removal of a previously authorized user or host from the infrastructure due to termination or transfer. SAN ports should be managed to ensure that any unused ports are explicitly disabled when not being used, such as when a previously connected server is removed from the SAN.

Configuration Information Protection

All attacks on a SAN start with obtaining information on the SAN's configuration, such as number and types of components, their configuration, and existing accounts. Without sufficient information it is virtually impossible to carry out a successful attack on a SAN environment. It is therefore critical that any information that provides details on how the IT infrastructure (including the SAN) is configured be carefully controlled. Some examples of information that can be used to plan an attack include:

- Network diagrams with TCP/IP addresses of SAN components
- SAN diagrams with component information
- Lists of usernames and users
- Inventory lists of components with firmware revisions

All such information should be labeled appropriately and its distribution restricted to only IT personnel with a confirmed need to know. When it is necessary to share this information with outside agencies (such as vendors when creating a Request for Proposal (RFP)). the information should be distributed utilizing positive controls, such as a password-protected view-only Adobe Acrobat PDF document.

11. SECURITY MAINTENANCE

Management of functions supported by the SAN should be divided up among personnel to ensure that no single person has control over the entire SAN. For example, one individual should be responsible for managing the storage systems, one responsible for configuring the SAN hardware itself, and a different individual should be responsible for managing the hosts connected to the SAN. When a change needs to be made it should be requested utilizing the change management system (see previous discussion), reviewed by all personnel involved, and thoroughly documented.

Limit Tool Access

Many Fibre Channel Host Bus Adapter (HBA) vendors provide the capability to change the world wide name of an HBA. This is usually accomplished via either a host-based utility or a firmware utility that gets executed when the host is booted. In the case of a host-based utility, such utilities should be removed and the host should be regularly scanned to ensure that they have not been

reinstalled. For management purposes the utilities should be copied to a CD-ROM and kept locked up until needed. For firmware-based utilities, many vendors provide the ability to disable the utility at boot time.

Note that in either case changing the WWN of an HBA usually requires that the host be rebooted. Monitoring of the environment should detect any unscheduled reboots and report them immediately. Also, any switches that the host is connected to should detect the change in the WWN and report an entry in its internal log; monitoring of these logs should also be performed and a security report issued when such changes are detected.

Limit Connectivity

The management ports on most SAN components are arguably the weakest points in terms of security. Most utilize a standard TCP/IP connection and some form of Web-based or telnet protocol to access the management interface. In most environments these connections are utilized infrequently—usually only when making a change to the configuration or requesting access to a log for auditing purposes. To maximize security and defeat denial-of-service forms of attacks, the port on the Ethernet switch that these interfaces are connected to should be disabled when they are not being used. This minimizes the number of potential attack points within the SAN.

Note: If a host requires network access to a storage system to perform its functions, disabling the port may not be possible.

Secure Management Interfaces

LAN connections to management interfaces should be secured utilizing some form of TCP/IP encryption such as Secure Sockets Layer (SSL) for Web-based interfaces or Secure Shell (SSH) for command-line interfaces. This can ensure that even in the event an attacker does manage to gain access to a management LAN, it will be difficult for them to gain any useful information, such as usernames and passwords.

12. HOST ACCESS: PARTITIONING

Partitioning defines methods to subdivide networks to restrict which components have access to other components. For Fibre Channel SANs this involves two distinct networks: the LAN to which the management interfaces of the components are connected and the SAN itself.

The network management interfaces for all SAN components should be connected to an isolated LAN (a VLAN). One or two management stations should be configured into the VLAN for management purposes. If a host requires LAN access to SAN components to function, a dedicated Network Interface Card (NIC) should be used in that host and included in the VLAN. For maximum security there should be no external routes into this management LAN.

The SAN itself should be partitioned using zoning. There are two forms of zoning: soft (or world wide name) zoning, which restricts access based on the world wide name (WWN), and hard zoning, which restricts access based on the location of the actual physical connection. Soft zoning is generally easier to implement and manage, since changes to zones are done entirely via the management interface and don't require swapping physical connections. However, should an attacker manage to gain control of a host connected to a SAN and fake the world wide name of another server (sometimes referred to as *WWN spoofing*), they could potentially gain access to a broader range of the storage on the SAN. Hard zoning requires slightly more effort when making changes, but it provides a much higher level of security, since an attacker would have to gain physical access to the SAN components to gain access outside the server they subverted. Note that for most current SAN switches, hard zoning is the default form of zoning.

A relatively new partitioning capability provided by some switch vendors is the concept of a virtual SAN, or VSAN. VSANs are similar to VLANs on an Ethernet network in that each VSAN appears to be a fully separate physical SAN with its own zoning, services, and management capabilities, even though multiple VSANs may reside on a single physical SAN switch. Strict segregation is maintained between VSANs, ensuring that no traffic can pass between them.

Finally, the storage systems themselves should be partitioned utilizing LUN masking, which controls which servers can access which LUNs on the storage system. Most modern SAN storage systems provide some form of LUN masking.

Combining VSANs and port zoning with LUN masking on the storage system provides a degree of defense in depth for the SAN, since an attacker would need to penetrate multiple separate levels of controls to gain access to the data.

S_ID Checking

When packets are transmitted through a SAN, they usually contain two fields that define where the packet originated: the source ID (S_ID) and the destination ID (D_ID). Under some configurations, such as soft zoning, the S_ID may not be validated, allowing an illegal host on the SAN to send packets to a storage server.

Some switch vendors provide the capability to force S_ID checking under all configurations; if this capability is available it should be enabled. Note that hard zoning (discussed earlier) will minimize the need for S_ID checking, since the available path for any SAN traffic will be strictly controlled.

Some high-end storage systems provide an even stricter method of defeating S_ID attacks, called *S_ID lockdown*. This SID feature provides additional security for data residing within the system. Since a WWN can potentially be spoofed to match the current WWN of another HBA, a host with a duplicate WWN can gain access to the data destined for the spoofed HBAs. S_ID lockdown prevents an unauthorized user from spoofing the WWN of an HBA. When the S_ID lockdown feature is enabled, the source ID (SID) of the switch port to which the protected HBA is connected is added to the Virtual Configuration Management Database (VCMDB) record. Once an association between the HBA's WWN, the SID, and the fiber adapter is created, the HBA is considered locked. When a SID is locked, no user with a spoofed WWN can log in. If a user with a spoofed WWN is already logged in, that user loses all access through that HBA.

13. DATA PROTECTION: REPLICAS

Many practices can be implemented that can significantly enhance the security of Fibre Channel SANs, but it is virtually impossible to guarantee that no attack will ever succeed. Though little can be done after data has been stolen, having in a SAN multiple replicas of the data that are updated regularly can help an organization recover from an attempted denial-of-service attack (see the section titled "Denial-of-Service Attacks" for more details). This includes not only having backups but maintaining regular disk-based replicas as well. For example, performing a point-in-time incremental update of a clone of a LUN every four hours provides a recovery point in the event the LUN gets corrupted or deleted by an attacker. It is critical that all replicas, whether they are disk or tape based, be protected at the same level as the original data.

Erasure

Any data that is stored in a Fibre Channel SAN is generally stored on some form of nonvolatile media (disk drive, tape, and so on). When that media reaches the end of its useful life, such as when upgrading to a new storage system, it is usually disposed of in the most efficient manner possible, usually with little consideration that the media may still contain sensitive data.

Any media that may have ever contained sensitive data should undergo a certified full data erasure procedure before leaving your infrastructure or be disposed of by a vendor that can provide assurance that the media will undergo such a procedure and will be under positive control until the procedure occurs. For extremely sensitive data, certified destruction of the media should be considered. The same level of consideration should be given to any media that may have contained sensitive data at one time, such as disks used to store replicas of data (snapshots or clones).

Potential Vulnerabilities and Threats

To effectively understand how secure a SAN is, it is important to understand what potential vulnerabilities exist. This would also include the types of attacks it could potentially face.

Physical Attacks

Physical attacks involve gaining some form of physical access to the SAN or the data stored on it. This may involve gaining access to the SAN switches to plug in an illegal host to be used for other attacks, stealing the disk drives themselves, or stealing backup tapes. It may also involve even more subtle methods, such as purchasing used disk media to search them for data that hasn't been erased or "dumpster diving" for old backup tapes that may have been disposed of in the trash. The following are physical attack countermeasures:

- Solid physical security practices, such as access control to the datacenter and locking racks for equipment, will defeat most physical attacks.
- Security monitoring of the environment will detect any changes to the SAN, such as a new host attempting to log in and fabric topology changes.
- Host-based encryption of critical data will ensure that the data on any stolen media cannot be accessed.
- Hard zoning and VSANs will limit the amount of access an attacker can obtain even if they do manage to gain access to an unused port.
- Explicitly disabling any unused (open) ports on a SAN switch will prevent them from being used in the event an attacker does gain access. The attacker will be forced to unplug an existing connection to gain access, which should become immediately apparent in any environment with even minimal monitoring.
- Regular audits can detect any changes in the physical infrastructure.
- Implementing data erasure procedures can prevent an attacker from gaining access to data after old media has been disposed of.

Management Control Attacks

Management control attacks (see checklist, "An Agenda For Action For Management Control Attacks") involve an attacker attempting to gain control of the management interface to a SAN component. This involves accessing the LAN that the management interface is on and utilizing some form of username/password cracking technique or TCP/IP attack (buffer overflow) to gain control of the interface. This type of attack is usually the first phase in a more detailed attack or else an attempt to deny access to SAN resources.

Host Attacks

Host attacks have the greatest potential risk of occurring, since attacking operating systems via a TCP/IP network is the most widely understood and implemented form of attack in the IT industry. These types of attacks usually involve exploiting some form of weakness in the operating system. Once an attacker has gained control of the host, they can then proceed to attack the SAN. The following are host attack countermeasures:

- A solid initial security setup will minimize the number of potential vulnerabilities on a host.
- Strong password policies will minimize the risk of an attacker gaining access to the host.
- A formal change management system and regular and active auditing and monitoring will detect the changes an attacker will have to make to a host to gain access to the SAN.
- Hard zoning on the SAN and LUN masking will limit the amount of data an attacker may be able to gain access to if they manage to subvert a host on the SAN.
- Defense in depth will reduce the probability of an attacker gaining access to a host in the first place.
- Timely security maintenance will ensure that an attacker cannot penetrate the host utilizing an unused account.
- Installing security updates in a timely manner will ensure that an attacker cannot exploit known vulnerabilities in the host's operating system.
- Regular auditing can detect changes in the host environment that may indicate an increased level of vulnerability.
- Classification of the data in the SAN can ensure that each host is protected at the level that is appropriate for the data it can access.

World Wide Name Spoofing

WWN spoofing involves an attacker assuming the identity of another host by changing the WWN of an HBA to gain access to that host's storage. This type of attack can occur in one of two ways: by subverting an existing host and changing its existing WWN or by installing a new host that the attacker controls on the SAN. Note that changing the WWN name of an HBA requires a host to be rebooted, which should be easily detectable with standard monitoring tools. The following are WWN spoofing countermeasures:

- Installing a new host requires physical access to the SAN, which can be defeated by the methods described in the section titled "Physical Attacks."
- Partitioning the SAN utilizing hard zoning tightly controls what resources an existing host can access, even if its WWN changes.
- Enabling port binding on the switch to uniquely identify a host by WWN and port ID on the fabric.
- Enable S_ID lockdown if the feature is available.

An Agenda for Action for Management Control Attacks

The following are management control attack countermeasures (Check All Tasks Completed):

_____**1.** Setting up the initial security utilizing strong security policies will increase the ability of the SAN to resist these types of attacks.

_____**2.** Strong password policies will hinder these types of attacks by making it difficult for an attacker to guess the passwords.

_____**3.** A formal change management system and regular auditing will allow any successful attacks to be detected.

_____**4.** Partitioning these interfaces into a VLAN will minimize the number of potential avenues of attack.

_____**5.** Defense-in-depth will force an attacker to penetrate many layers of security to gain access to the management interfaces, significantly decreasing the probability of success and increasing the probability of detection.

_____**6.** Regular security maintenance will ensure that an attacker cannot gain access by using an old account.

_____**7.** Active monitoring will detect significant changes in LAN traffic going to these interfaces.

_____**8.** Limiting connectivity to management ports when not required can limit the available window for such an attack.

_____**9.** Regular auditing will detect any changes to the management environment and ensure that the security configuration is up to date.

_____**10.** Performing a vendor security review will ensure that the SAN components have been configured for the maximum level of security

- Changing the WWN of an HBA in an existing host requires the attacker to first subvert the host, which is addressed in the section titled "Host Attacks."
- Utilizing host-based encryption can prevent an attacker from reading any data, even if they do manage to subvert the SAN, since the host performing the spoofing should not have access to the encryption keys used by the original host.
- Ensuring the tools necessary to change the WWN of an HBA are not installed on any host can prevent an attacker from spoofing a WWN.

Man-in-the-Middle Attacks[1]

Man-in-the-middle attacks involve an attacker gaining access to Fibre Channel packets as they are being exchanged between two valid components on the SAN and requires the attacker have a direct connection to the SAN. These types of attacks are roughly analogous to Ethernet sniffer attacks whereby packets are captured and analyzed. Implementing this type of attack requires some method that allows an attacker to gain access to packets being sent to other nodes on the SAN (referred to as *promiscuous mode* on Ethernet LANs), which is not generally supported in the Fibre Channel protocol. The following are man-in-the-middle attack countermeasures:

- Since this type of attack requires that an attacker be physically plugged into the SAN, they can be defeated by the methods described in the section titled "Physical Attacks."
- Disable any port-mirroring features on a SAN switch if they are not being used. This prevents an attacker from gaining access to SAN configuration data.
- By utilizing host-based encryption the data contained in any intercepted packets cannot be read by the attacker.

E-Port Replication Attack

In an e-port attack, an attacker plugs another switch or a specially configured host into the e-port on an existing switch in the SAN. When the switch sees a new valid peer connected on the e-port, it will send it a copy of all its configuration tables and information. This method is not necessarily an actual attack in and of itself but a method to gain information to be used to perpetuate other attacks. The following are e-port replication attack countermeasures:

1. An attack in which an attacker is able to read, insert, and modify messages between two parties without either party knowing that the link between them has been compromised.

- Since this type of attack requires that an attacker be physically plugged into the SAN, they can be defeated by the methods described in the section titled "Physical Attacks."
- Enable switch and Fabric binding on the switch to "lock down" the topology and connectivity of the fabric after initial configuration and after any legitimate changes are made.

Denial-of-Service Attacks

Denial-of-service (DoS) attacks are designed to deprive an organization of access to the SAN and the resources it contains. These types of attacks can take many forms, but they usually involve one of the following:

- Saturating a component with so much traffic that it cannot perform its primary function of delivering data to hosts
- Taking advantage of a known vulnerability and crashing a component in the SAN
- Gaining access to the management interface and deleting LUNs to deprive the owner of access to the data

A new type of attack that has surfaced recently also fits into this category. An attacker gains access to the data, usually through a host, encrypts the data, and then demands payment to decrypt the data (that is, extortion). The following are DoS attack countermeasures:

- Partitioning the LAN that the SAN component management interfaces are on can prevent an attacker from ever gaining access to those components to implement a DoS attack. This includes disabling those interfaces when they are not in use.
- Defense in depth will force an attacker to defeat several security layers to launch the DoS attack, reducing the probability of success and increasing the probability of detection before the attack can be launched.
- Deploying VSANs will prevent DoS traffic on one SAN from interfering with the others in the event of a successful attack.
- Maintaining up-to-date protected replicas of all data can allow easy recovery in the event a DoS attack results in data being deleted or encrypted.

Session Hijacking Attacks

A session hijacking attack involves an attacker intercepting packets between two components on a SAN and taking control of the session between them by inserting their own packets onto the SAN. This is basically a variant of the man-in-the-middle attack but involves taking control of an aspect of the SAN instead of just capturing data packets. As with man-in-the-middle attacks, the attacker

must gain physical access to the SAN to implement this approach. Session hijacking is probably more likely to occur on the LAN in an attempt to gain access to the management interface of a SAN component. The following is a session hijacking attack countermeasure: Since this type of attack requires that an attacker be physically plugged into the SAN, they can be defeated by the methods described in the section titled "Physical Attacks." Table e51.1 summarizes the various best practices and the potential vulnerabilities they address.

14. ENCRYPTION IN STORAGE

Encryption is used to prevent disclosure of either stored or transmitted data by converting data to an unintelligible form called *ciphertext*. Decryption of the ciphertext converts the data back into its original form, called *plaintext*.

For environments that require even higher levels of security you can encrypt all transmissions (data and control) within the SAN utilizing a commercially available SAN encryption device. Also, for extremely sensitive data, host-based encryption should be considered. Most modern operating systems provide some form of encryption for their file systems. By utilizing these capabilities, all data is encrypted before it even leaves the host and is never exposed on the SAN in an unencrypted form.

The Process

Encryption simplifies the problem of securely sharing information by securely sharing a small key used to

encrypt the information. In a two-party system, a process similar to these steps would be followed.[2]

1. Alice and Bob agree on an encryption algorithm to be used.
2. Alice and Bob agree on a key to be used for encryption/decryption.
3. Alice takes her plaintext message and encrypts it using the algorithm and key.
4. Alice sends the resulting ciphertext message to Bob.
5. Bob decrypts the ciphertext message with the same algorithm and key as the original encryption process.
6. Any change in the key or encryption algorithm has to be agreed on between Alice and Bob. The process of converting to a new key or algorithm requires decrypting the ciphertext using the original key and algorithm and reencrypting with the new key and algorithm. It is important that the key management system used securely preserves the old key for as long as the data retention policy for that data prescribes. Premature destruction of the key will result in loss of data.

The secure exchange of data in a two-party system is typically accomplished using a public/private key mechanism. Protecting data at rest, however, is best handled with a symmetric (private) key because the data is accessed from fixed and/or known locations. Typically one host would use the same algorithm and key to encrypt the data when writing to disk/tape and to decrypt the data when reading from disk/tape. In the case of multipathing or situations in which multiple applications from different nodes will access the data, centralized key management is essential.

Throughout the remainder of the chapter, only symmetric-key encryption will be discussed and will be referred to simply as *encryption. Symmetric-key encryption*, as noted, refers to the process by which data is encrypted and decrypted with the same key. This method of encryption is more suited to the performance demands of data path operations. *Asymmetric-key encryption* refers to the process where encryption is performed with one key and decryption is performed with another key, often referred to as a *public/private key pair*. Asymmetric-key encryption is not well suited to encrypting bulk data at rest due to performance constraints and manageability.

Encryption Algorithms

The algorithm used can be any one of a variety of well-known cryptosystems described in the industry. The U.S. Federal Information Processing Standards (FIPS) document the Advanced Encryption Standard (AES[3]) and specify it as the industry-standard algorithm in the United States. AES is the most common algorithm implemented in the current encryption methods described as follows. Triple-DES (Data Encryption Standard) is still a certified algorithm by the National Institute of Standards and Technology (NIST) and may be used but is not recommended.[4]

Encryption algorithms typically operate on block lengths of 64 to 128 bytes. To encrypt longer messages an encryption mode of operation may be used, such as:

- CBC—Cipher-block chaining
- CTR—Counter
- XTS—Tweakable narrow block
- GCM—Galois/counter mode

The CBC, CTR, and GCM modes of operation used for encryption require the use of an initialization vector (IV), or nonce. The IV is a seed block used to start and provide randomization to the encryption process. The same IV and key combination must not be used more than once. XTS is the only one of the four that does not require an IV but instead has a second key called the *tweak key*.

In the event the length of the message to be encrypted is not a multiple of the block size, it may be required to pad the final block.

Key Management

The protection potentially afforded by encryption is only as good as the management, generation, and protection of the keys used in the encryption process. Keys must be available and organized in such a fashion that they can be easily retrieved, but at the same time, access to keys must be tightly controlled and limited only to authorized users. This attention to key management must persist for the lifetime of the data, not just the lifetime of the system that generates or encrypts the data. Generation of keys should follow some simple guidelines:

- The key generated must be random, for example, as specified by FIPS 186-2.[5] There can be no predictability to the key used for encryption; pseudorandom number generators are not acceptable for key generation.
- Key length for AES can be 128, 192, or 256 bits.

Once the keys are generated, their protection is crucial to guaranteeing confidentiality. This requires the following:

- *Secure access to the key management solution.* The key management solution must provide a method to guarantee that unauthorized access to keys is restricted. This access restriction should also extend to the facility for generating and managing keys. This can be accomplished via a number of mechanisms including secure

5. http://csrc.nist.gov/publications/fips/fips186-2/fips186-2-change1.pdf.

Web, smart cards, or split key arrangements. The key management solution must also protect against physical tampering as outlined in FIPS 140-2.[6]

- *Backup and recovery facilities for configuration and key information.* This information itself must be encrypted and stored to a secure backup medium (for example, a smart card). The keys used for encryption must never be visible in plaintext outside the key management solution and, under most circumstances, should not be visible at all. For additional security, the recovery of the configuration/keys should be performed by a group of security administrators. This eliminates the potential for misuse due to corruption of a single administrator and utilizes a group key recovery model where M of *N* (that is, 2 of 3, 3 of 5, and so on) or a quorum of administrators is needed to reconstruct an encrypted configuration.
- *The ability to apply high availability and business continuity practices and protocols* to key stores.
- *The ability to store keys and identify where they have been used for the lifetime of the data.* This covers data that is written to tape and that may be read up to 30 years later.
- *Integrity checking of keys.* This is particularly important if there are no integrity checks on the data.
- *Comprehensive logging and regular auditing* of how and when the keys are used.

Key management can be distributed or centralized. A common implementation of these requirements is a key management station that can reside either online with the encryption engine or out of band via TCP/IP. The key management station provides a centralized location where keys can be managed and stored securely and meet the stringent standards of FIPS 140-2. At this point, there are very few certified, standalone key management systems.

Configuration Management

In configuring any of the methods for encrypting data described here, there are several common steps that need to be executed. The unit to be encrypted needs to be identified (for example, record, file, file system, volume, tape) and an associated key needs to be generated. This configuration information needs to be recorded, securely transmitted to the encryption engine, and securely stored for the lifetime of the encrypted data.

To ensure access to the encrypted data, the configuration must account for all paths available to the data and identify which applications, hosts, or appliances will access the data through those paths. Each needs access to the algorithm and key to be able to read/write uniformly from each path. In addition, replicas (for example, snaps, clones, and mirrors) need to be identified and associated with the original source data to ensure that they can also be correctly decoded when read.

6. http://csrc.nist.gov/cryptval/140-2.htm.

15. APPLICATION OF ENCRYPTION

Encryption is only one tool that can be applied as part of a comprehensive information security strategy, and as such, should be applied selectively, only where it makes sense. Determining exactly where and how this takes place begins with an assessment of risks to the data, the suitability of encryption to address the risk, and then, if appropriate, the options for deployment of the technology.

Risk Assessment and Management

Risk assessment is a calculation that requires three key pieces of information: the number and nature of threats, the likelihood of a threat being realized in the form of an attack, and the impact to the business in the event the attack succeeds. Let's consider these in the context of a decision of whether it is appropriate to deploy encryption technology.

As administrators manage the flow of data from application to storage, they need to understand the nature of possible threats to the data and the likelihood of occurrence. These threats may take the form of:

- Unauthorized disclosure
- Destruction
- Denial of service
- Unauthorized access
- Unauthorized modification
- Masquerade[7]
- Replay[8]
- Man-in-the-middle attacks

These threats may occur at any point from where the information is generated to where it is stored. For each of these threats, an evaluation must be made as to the likelihood of attacks occurring and succeeding in light of existing protection measures. If any attack is determined to be likely, the value of the information subject to threat must be also considered. If the value to the business of the data being threatened is low, it ultimately may not warrant additional protection.

7. An attack in which a third party tries to mislead participants in a privileged conversation using forged information.

8. A form of network attack in which a valid transmission is maliciously or fraudulently repeated or delayed.

For those risks deemed to be significant, another calculation is required: are the tradeoffs of the proposed solution (in this case, encryption) worth making in context of the level of threat to the data. Considerations should include:

- Cost to deploy
- Level of threat
- Severity of vulnerability
- Consequences
- Detection time
- Response time
- Recovery time
- New risks introduced by encryption, such as premature loss of keys

In this case, by restricting access to the information via authentication and authorization, the administrator can identify who has rights to use the information as well as who has attempted to use the information. Access privileges can be granted at various points in the information flow: at the application, operating system, network, and storage platform layers. If these measures are deemed insufficient, encryption might provide another layer of defense.

Modeling Threats

To make this process more specific to the problem at hand, Figure e51.1 illustrates some of the risks to data in the enterprise. By understanding the attacks that can occur, administrators can determine where encryption may help to protect data and where it would not be applicable. Figure e51.1 shows the following:

- Encrypting the information at the application level protects against unauthorized viewing of information at the operating system (user) and network levels, as well as protects against media theft. However, encryption at this level will not protect against unauthorized access at the application level (as the information is decrypted at that point) nor root access from the operating system unless strong application access controls are in place.
- Encrypting the information at the host or operating system level protects against unauthorized viewing of information at the network level as well as protects against media theft. Encryption at this level will not protect against unauthorized access at the application or operating system level as the information is decrypted at that point. Access control technology would be required to provide additional security at the operating system and application levels.
- Encrypting the information in the network protects against unauthorized viewing of information from the encryption device to the storage device in the network as well as protects against media theft. Encryption at this level will not protect against unauthorized access at the application or operating system level or in the network up to the encryption device as the information is decrypted at that point.
- Encrypting the information at the device level protects against media theft. Encryption at this level will not protect against unauthorized access at the application or operating system level or in the network as all data external to the device is unencrypted.

Use Cases for Protecting Data at Rest

The following are some specific use cases that warrant deployment of encryption of data at rest. The primary use

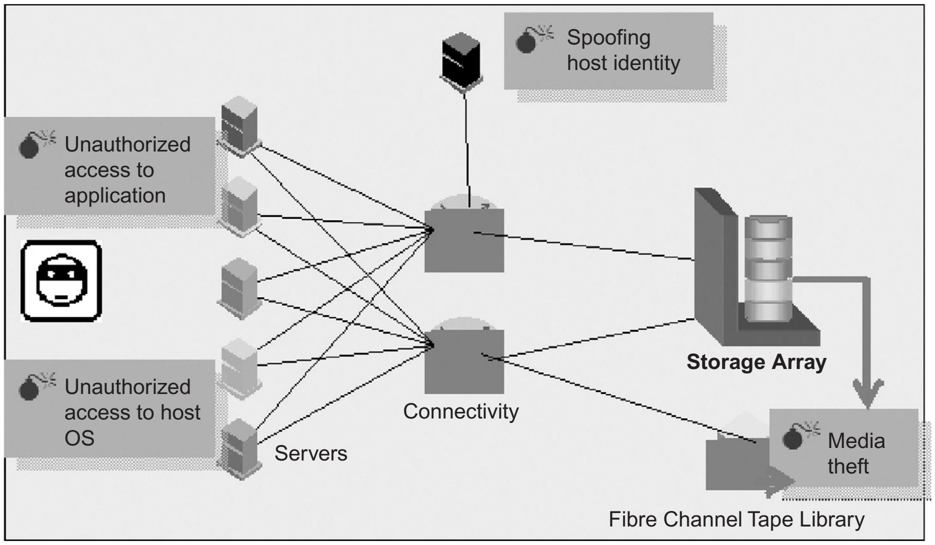

FIGURE e51.1 Threats to plaintext customer data.

case is protecting data that leaves administrators' direct control. Some examples of this situation include:

- Backup to tape
  - Tapes that are sent offsite
- Removal of disk for repair
  - Key-based data erasure for removed disk or array for return
  - Data sent to a disaster recovery or remote site
- Protection of data between and in disaster recovery sites
  - Consolidating data from many geographies to a single datacenter while still following each country's security laws
  - Using Type 1 encryption to share data between multiple secure sites
  - Data in harm's way (used for military applications such as planes, Humvees, embassies)
- Data extracts sent to service providers and partners
  - Outsourcing scenarios where sensitive data resides in vendor systems

A second use case is protecting data from unauthorized access in the datacenter when existing access controls are deemed to be insufficient. Some examples of this situation are:

- Shared/consolidated storage used by numerous groups
  - haring a single datacenter/array for multiple levels of security
  - Sharing a platform between an intranet and Internet for consolidation
- Protecting data from insider theft (employees, administrators, contractors, janitors)
- Protection of application/executables from alteration

In addition, data encryption is mandated or recommended by a number of regulations. Deploying encryption will enable or aid in compliance. Selected examples of these regulations include:

- *Sarbanes-Oxley Act.* U.S. regulation with respect to disclosure of financial and accounting information.
- *CA 1798 (formerly SB-1386).* California state legislation requiring public disclosure when unencrypted personal information is compromised.
- *HIPAA.* U.S. health-care regulation that recommends encryption for security of personal information.
- *Personal Information Protection Act.* Japanese regulation on information privacy.
- *Gramm-Leach-Bliley Act.* U.S. finance industry regulation requiring public disclosure of personal data breaches.
- *EU Data Protection Directive.* European Union directive on privacy and electronic communications.
- *National data privacy laws.* Becoming pervasive in many nations, including Spain, Switzerland, Australia, Canada, and Italy.

Use Considerations

There are additional factors to consider when using encryption:

- Data deduplication at the disk level may be affected. Any good encryption algorithm will generate different ciphertext for the same plaintext in different circumstances. As a result, algorithms for capacity reduction by analyzing the disk for duplicate blocks will not work on encrypted data.
- Encrypted data is not compressible. Lossless compression algorithms could potentially expand as often as they compress encrypted data if applied. This will impact any WAN connectivity needing to transmit encrypted traffic.
- There is overhead in converting current plaintext data to ciphertext. This is done as a data migration project, even when it is done in place. Host resources, impact to CPU utilization, and running applications must be considered.
- An additional benefit to encrypting data at any level described is the ability to provide data shredding with the destruction of the key. This is especially efficient when there are multiple, distributed copies of the data encrypted with the same key. For the data to be considered shredded, all management copies of the key need to be destroyed for all security administrators, smart cards, backups, key management stations, and so on. Key destruction must follow similar guidelines as to the data erasure outlined in NIST SP 800-88.

Deployment Options

As we have seen, the use cases discuss why encryption would be used and the threats being protected against determine where encryption should be deployed. The following sections discuss in further detail deployments at each layer of the infrastructure.

Application Level

Perhaps the greatest control over information can be exercised where it originates, from the application. The application has the best opportunity to classify the information and manage who can access it, during what times and for what purpose. If the administrator has concerns/risks over the information at all levels in the infrastructure, it makes sense to begin with security at the application level and work down. In this case application-based encryption should be an option. Adding encryption at the application level allows for granular, specific information to be secured as it leaves the application. For example, a database could encrypt specific rows/columns of sensitive information (for example, Social Security numbers or

credit-card numbers) while leaving less sensitive information unencrypted. Attempts to snoop writes-to-disk or to read-data directly from disk without the application decrypting it would yield useless information.

Encryption at the application level provides security from access at the operating system level as well as from other applications on the server as shown in Figure e51.2. The application would still need to provide user authentication and authorization to guarantee that only those with a need to know can access the application and the data. If the application lacks these strong access controls, application-based encryption will provide no additional security benefit. End-user activities with data after it is converted to clear text are potentially the highest security risk for organizations.

There are some drawbacks to encrypting at the application level. First, encryption is done on a per-application basis. If multiple applications need encryption, each would have to handle the task separately, creating additional management complexities to ensure that all confidential data is protected. Second, application-level encryption solutions are typically software based. Encryption is a CPU-intensive process and will compete with normal operating resources on the server. In addition, the encryption keys will be stored in dynamic, nonvolatile memory on the server. If a hacker were to break into the server and find the keys, the information can be decrypted. Externalizing the encryption engine or key manager may address these issues at the expense of additional solution cost. An external key manager also enables clustered applications to share key information across nodes and geography (provided that each node can supply a secure channel from the server to the key manager.) If FIPS 140-2 compliance is a requirement for the encryption solution, an external appliance is typically used.

Application-based encryption also presents challenges in the area of rekeying. Any effort to rekey the data (to protect the integrity of the keys) will have to be done by the application. The application will need to read and decrypt the data using the old key and reencrypt and rewrite to disk using the new key. The application will also have to manage old and new key operations until all the previously encrypted information is reencrypted with the new key. This most likely will be done while the application is handling normal transactions, again presenting resource contention issues.

Another challenge occurs with the introduction of ediscovery solutions in the enterprise. Encryption at the application level will expose only encrypted information to other applications (including backup) and devices in the stack. Any attempt to perform analysis on the data will be useless as patterns and associations will be lost through the randomization process of encryption. To accomplish any analysis the ediscovery applications will need to be associated and linked to the application performing encryption to allow for a decryption of data at a level outside of the application, and a possible security risk could be introduced.

Application-based encryption (see Figure e51.2) must also account for variable record lengths. Encryption schemes must pad data up to their block size to generate valid signatures. Depending on the implementation, this may require some changes to application source code.

Application-based encryption doesn't take into account the impact on replicated data. Any locally replicated information at the storage layer, that is, a clone, does not have visibility into the application and the keys

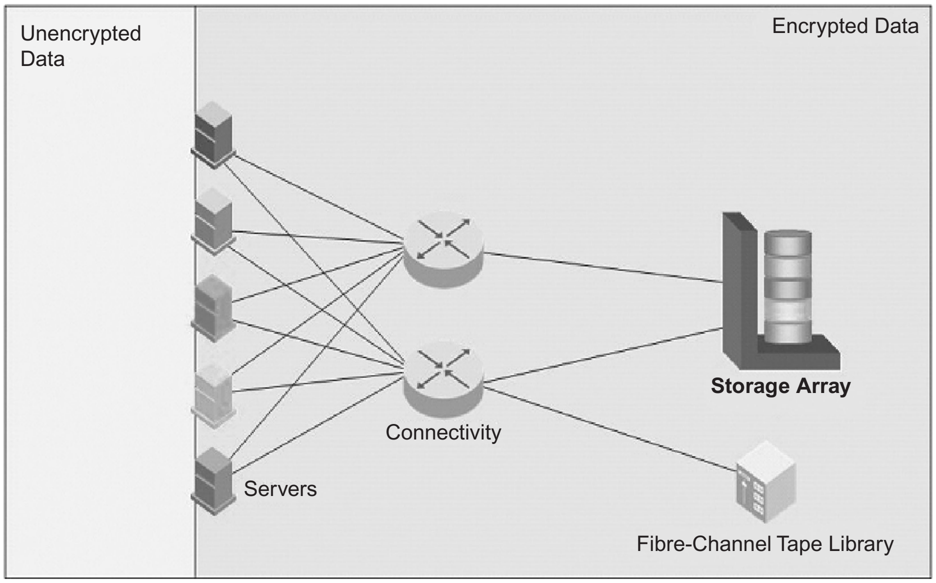

FIGURE e51.2 Coverage for application-based encryption.

and the application does not have visibility into the replication process. Key management can become more complex. In addition, compression in the WAN is impossible for remote replication of the encrypted information causing WAN capacity issues.

Host Level

Encrypting at the host level provides very similar benefits and tradeoffs to application-based encryption. At the host level, there are still opportunities to classify the data, but on a less granular basis; encryption can be performed at the file level for all applications running on the host (as shown in Figure e51.3). However, there are options for a host-based adapter or software to provide encryption of any data leaving the host as files, blocks, or objects. As with application-level implementations, the operating system must still provide user authentication and authorization to prevent against host-level attacks. If these strong access controls are absent, host-level encryption will provide no additional security benefit (aside from protection against loss or theft of media). If implemented correctly and integrated with the encryption solution, they can provide some process authorization granularity, managing which users should be allowed to view plaintext data.

At the host level, encryption can be done in software, using CPU resources to perform the actual encryption and storing the keys in memory, or offloaded to specialized hardware. Offload involves use of an HBA or an accelerator card resident in the host to perform the actual encryption of the data. In the case of the HBA the encryption can be performed in-band and is dedicated to the particular transport connection from the host, that is, Fibre Channel. For an accelerator card approach, the encryption is done as a look-aside operation independent of the transport. This provides flexibility for host connectivity but increases the memory and I/O bus load in the system. In either case the host software would control the connection to the key manager and management of the keys.

There may be a need in the enterprise for the host-based encryption solution to support multiple operating systems, allowing for interoperability across systems or consistency in the management domain, something to consider when evaluating solutions. In addition, when encryption is implemented at the host level, there is the flexibility of being storage and array independent, allowing for support of legacy storage with no new hardware needed. Host-based encryption does present a challenge when coupled with storage-based functionality, that is, replication. If replication is employed underneath the host encryption level the host implementation must have the ability to track replicas and associate encryption keys, eliminating the need for users to manually manage the replication and encryption technology. As host encryption supplies encrypted data to the array, remote replication would transmit encrypted, uncompressible data. This would severely impact WAN performance.

As with application-based encryption, ediscovery solutions in the enterprise pose additional complexities. Encryption at the host level will expose only encrypted information to other hosts and devices in the stack, introducing the same challenges with analysis as those described in the prior section.

As encryption is performed at the host level, the data can be of variable record length. Similar to the application-based approach, the encryption solution can add information to the encryption payload to allow for a digital signature or cryptographic authentication. This would prevent a “man-in-the-middle” from substituting bad packets for the good encrypted packets from the host.

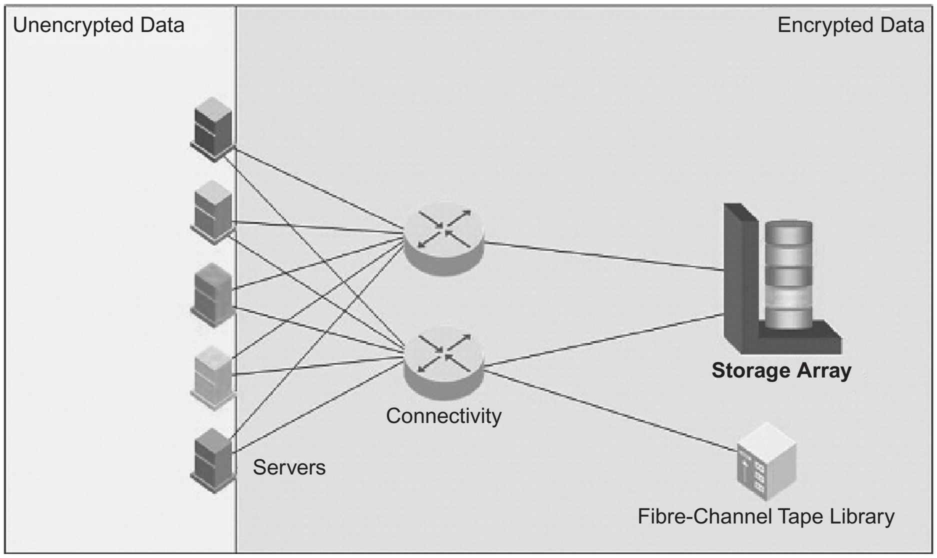

FIGURE e51.3 Coverage for host-based encryption.

Network Level

If the threats in the enterprise are not at the server, operating system, or application level, but instead at the network or storage level, then a network-based appliance approach for encryption may work best. This approach is operating system independent and can be applied to file, block, tape, Fibre Channel, iSCSI, or NAS data. Encryption and key management are handled entirely in hardware and run at wire speed for the connection. The appliance presents an "unencrypted side" and "encrypted side" to the network. Encryption can be designated on a per block, file or tape basis and the keys maintained for the life of the data. Appliances available today are typically FIPS 140-2 level 3 validated.

There are two implementations for a network-based appliance design: store-and-forward or transparent. The store-and-forward design appears as storage to the server and a server to the storage, and supports iSCSI, Fibre Channel, SAN, NAS, and tape. An I/O operation comes to the appliance, is terminated, the data encrypted, and then forwarded to the destination storage device. This approach adds latency and as a result, some form of "cut-through" ideally needs to be offered to minimize the impact of the device for nonencrypted traffic. In addition, to appear as both server and storage, the store-and-forward appliance either needs to spoof the identities of the attached devices or rely on robust security practices to counteract the attempts to circumvent the appliance. While there may be a latency penalty for encrypting data through the appliance, the store-and-forward-based design has the benefit of allowing the attached storage devices to be rekeyed in the background. This is performed with no disruption to host operations as all I/O operations to the storage are handled independently of the host. There may still be some performance impact to the rekeying process, depending on the I/O load on the encryptor.

The transparent approach provides a flow-through model for the data being encrypted, supporting Fibre Channel SAN and tape. The appliance inspects SCSI headers as data flows through the appliance and encrypts only the data payloads that match preset source/destination criteria in the appliance configuration. The latency associated with this approach is minimal. The transparent design does, however, have a drawback when the encrypted data needs to be rekeyed. Unlike the store-and-forward design, the device is essentially transparent in the data flow, requiring the host to perform the reads and writes required in rekeying the encrypted data. This process can be done by a separate host agent and could be performed while normal operations are in process.

For block-based implementations, the size of the encrypted data cannot increase. This means no additional information can be added to the encrypted payload (for example, a digital signature). This is not true for file or tape-based encryption where the record information may be variable. As noted in the discussion on standards, the IEEE is working to provide standards for encrypting block data at rest, in IEEE P1619.

There may be a need in the enterprise for the encryption to support multiple operating systems, allowing for interoperability across systems or consistency in the management domain. In addition, when encryption is implemented at the network level, there is the flexibility of being storage- and array-independent, allowing for support of legacy storage—at the cost of adding new hardware. Hardware in this case is added in increments of ports, typically two at a time, adding to the power, package, and cooling issues currently facing enterprises today. In addition, adding appliances in these increments can add complications in managing additional devices in the enterprise. Network-level encryption does present a challenge when coupled with storage-based functionality such as replication. If replication is employed underneath encryption at the network level, the implementation must have the ability to track replicas and associate encryption keys, eliminating the need for users to manually manage the replication and encryption technology. As network-level encryption supplies encrypted data to the array, remote replication would transmit encrypted, uncompressible data. This would severely impact WAN performance.

There are also implementations moving to use data integrity features as part of the protocols. Encryption in the network level (see Figure e51.4) would encrypt both the data and the data integrity, resulting in mismatches at this level of checking performed at the arrays.

Network-level encryption doesn't take into account the impact on replicated data. Any locally replicated information at the storage layer, that is, a clone, does not have visibility into the network device management and the keys and the network device does not have visibility into the replication process. Key management can become more complex and more manual. In addition, compression in the WAN is impossible for remote replication of the encrypted information causing WAN capacity issues.

Device Level

Encryption at the device level—array, disk, or tape—is a sufficient method of protecting sensitive data residing on storage media, which is a primary security risk many organizations are seeking to address. All data written to the device would be encrypted and stored as such and then decrypted when read from the device. Encryption at this level would be application and host independent and can be transport independent as well. When addressing

media theft, the granularity for encryption, and keys, can be at the disk or tape level. As demonstrated in Figure e51.5, exposure for unencrypted data is increased as compared to the previous implementation examples.

Array-Level Encryption

There are a number of design points for encryption in the array, that is, at the disk or controller level. Design considerations for encryption include the interfaces to the array, software support, performance, FIPS validation, key management, and encryption object granularity to name a few. The intent is to have the encryption implementation transparent to the hosts attached while protecting the removable media. The connected hosts may not be knowledgeable of the encryption implementation but may be with respect to management and performance. All aspects of the design must be considered.

One possible approach is to implement the encryption in the disk drive, at the back end of the array. Some points to consider:

- As encryption is on a per-drive basis, the computes required are included in the drive enclosure, allowing for a scalable solution, adding encryption with every unit. The downside to this is cost to the functionality that is added with every unit. So while performance scales, so can cost.

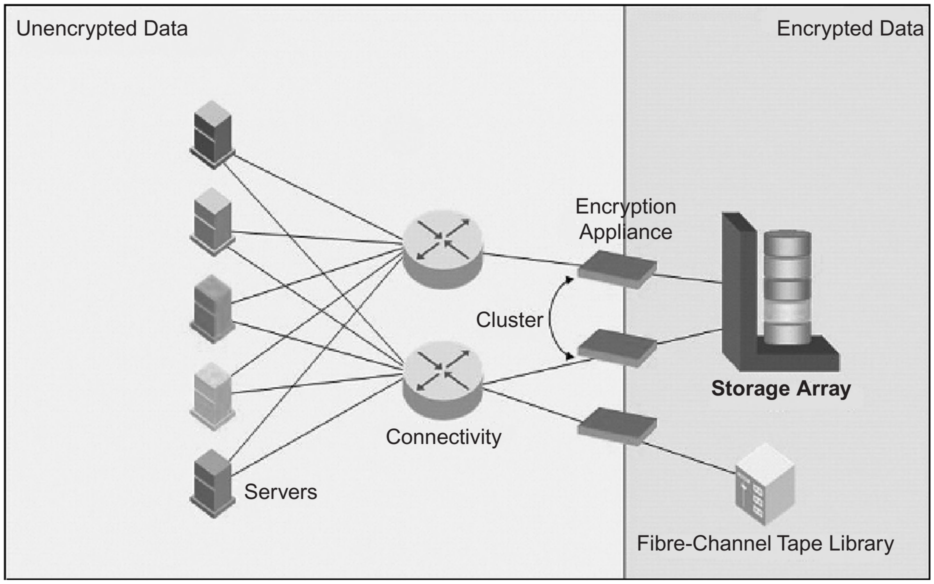

FIGURE e51.4 Coverage for network-based encryption.

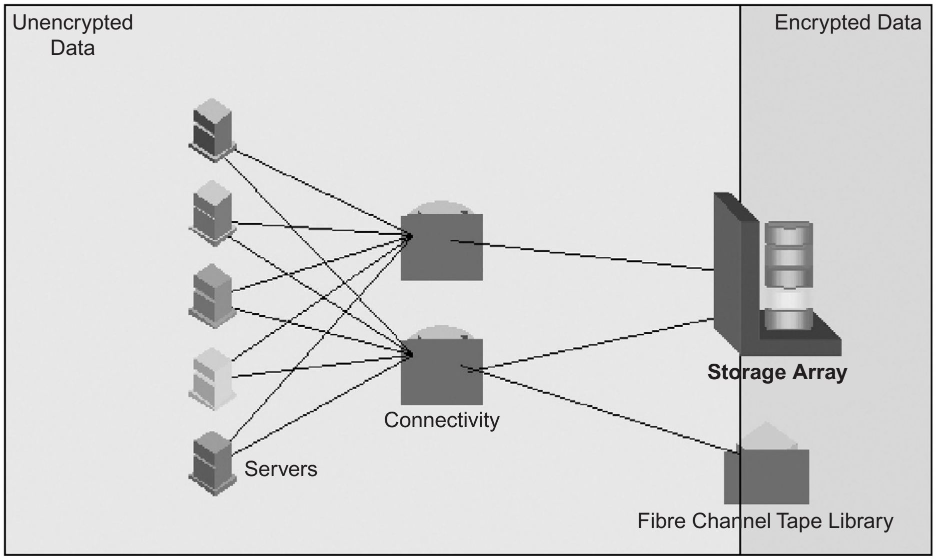

FIGURE e51.5 Coverage for device-based encryption.

- Customers might be unable to verify that encryption is enabled and functioning on the array, because data is always plaintext when it is external to the disk drive.
- Any approach to encryption at this level would also require interoperability of the encryption implementation across drive vendors to maintain flexibility and customer choice.
- Bulk drive encryption would not provide key granularity at the LUN/device level, which in many cases would eliminate the possibility of erasing specific confidential projects via key deletion.
- Last, as driven by the Trusted Computing Group, encryption at this level may follow a different path for validation, an alternative to FIPS 140 yet to be developed. Without a standard to evaluate it is impossible to understand the disk drive encryption validation proposal.

Another approach might be to implement encryption in the I/O controller connected to the disk drives. Some points to consider for this potential implementation are:

- Encryption is on the interface level and is required to support full wire speed versus interface speed in the drive approach.
- The cost model would be based on a single controller versus tens of drives connected to a single controller.
- The controller approach has the ability to perform encryption at the I/O level, allowing the granularity for key management to be at the LUN or disk level. This approach allows for future support of LUN-based erasure and logical data management.
- The controller approach is drive-independent, not relying on any specific vendor or interface, allowing for all standard tools and failure analysis to be performed.
- In supporting encryption at the controller level the crypto boundary can be well defined, allowing for FIPS 140-2 validation.
- Encryption and key control would be separate from the disk drive containing the encrypted data. This allows the customer to validate the encryption functionality is working and not be concerned with keys leaving with a removed disk drive.

An alternative to the encryption option for the protection against media theft is data erasure. It addresses the same primary use case: protection of disk media containing sensitive data and is available today, as erasure services (for removed drives) and software (for in-frame erasure). Erasure overwrites data multiple times, in accordance with the Department of Defense specification 5220.22-M, removing the data from the media. One consideration is that a minority of drives are not erasable for mechanical reasons.

Tape Encryption

As part of normal operations, data is frequently written from storage devices to tape for backup/data protection or third-party use. Data on tape cartridges becomes susceptible to theft or loss due to the size of the tape cartridge and quantity of the number of tapes to track during normal backup operations. To best protect the data on tape against unintended/unauthorized viewing, it can be encrypted. There are several approaches to encrypting tape as part of the backup operation:

- Reading encrypted data from application/disk and writing as encrypted data to tape
- Reading unencrypted data from application/disk and encrypting as part of the backup application
- Encrypting any/all data sent to tape via an encryption appliance in the network
- Encrypting any/all data written to the tape via an encrypting tape library or tape device

Tape encryption also presents key management challenges. Tapes may be stored for an extended period of time before an attempt is made to recover information. During the normal process of managing encrypted data, the application may have rekeyed the data on disk, updating all data on the disk to use a new key. This process would present the application with active data using one key and data on tape using an older key. The application must be therefore be able to manage keys for the lifetime of the data, regardless of where the data is stored. The following are tape encryption deployment options.

Application Level

Backup is typically another operation running on a host as a peer to the encrypting application. Any peer application or process will read data from the storage array as encrypted data. This allows the backup process to write already encrypted data to tape without having to perform the encryption itself. It will, however, prevent data compression during the backup process, as encrypted data is not compressible. Because typical compression ratios reduce data volumes anywhere from 2:1 to 4:1, this will impact performance of the backup process if a large amount of bulk data is encrypted.

Applications providing encryption can also provide access for authorized peer applications to read data in encrypted or unencrypted form. This would allow a backup application to read data in unencrypted form and allow for compression followed by encryption to be performed as part of the backup process.

Operating System/Host

Backup is another process on the host when using host-based encryption. The encryption process in the host operating system has the option of allowing the backup

process to read data in encrypted or unencrypted form. If the authorization module determines that the backup process can read plaintext data, backup will receive decrypted data to be sent to tape. Encryption will also need to be performed by the backup application to allow for writing secure tapes. The backup process could take advantage of compression in this data flow. If the backup process is not allowed to view decrypted data, it will read encrypted data from disk and write it as such to tape. As in the application-based approach, compression may not be able to be utilized on this encrypted data, creating potential performance issues. In addition, the encryption engine for the host will have to maintain the keys for the lifetime of the data to ensure that decryption can take place in the event a restore from tape is needed.

In the Network

If an encryption appliance is placed in the network, backup can be handled in one of two ways. If backup is volume based, any data read from the storage array may already be encrypted. The backup application will read the encrypted data and write it directly to tape. In this scenario, there would be no benefit of compression in the data path. If the backup is file or incremental based, the backup process would read the data through the appliance, decrypting it in the process, and could then write the data to tape. To provide encryption, a tape encryption appliance would be positioned in front of the tape device, compressing and encrypting the data as it is written to tape. The tape encryption appliance would manage the keys for the lifetime of the tape.

At the Tape Library/Drive

Data can be encrypted at the tape drive level, independent of the backup process and application software. All encryption is performed at the device, or library, when data is written to the tape and decryption performed at the drive when data is read from the tape. The backup application deals with nothing but plaintext data. The tape drive or library can be the management interface to the key manager, requesting generation of keys for new tapes written and retrieval of keys for each tape read. Association of keys to tapes is managed at the key manager appliance. In some cases the key manager can be integrated to work cooperatively with a volume pool policy defined with backup application. Jobs directed to use tapes in a pool associated with this policy begin with a request by the drive or library for an encryption key only when the backup or restore job uses tapes in this volume pool.

16. SUMMARY

Security is a complex and constantly evolving practice in the IT industry. Companies must recognize that threats to information infrastructures require vigilance on the part of IT managers and the vendors they rely on.

The management, integrity, and availability of your data should be your first priority. As this analysis has shown, basic security best practices can be implemented to greatly increase the security of your Fibre Channel SAN and the data it contains. The available avenues of attack are minimized by carefully controlling access to resources, both physically and logically.

While many storage vendors are making extensive investments in the security of their SAN products, they also recognize that it is impossible to predict every possible current and future combination of threats that might impact an IT environment. Ensure that your vendor constantly monitor changes and advances in security threats and technology, and updates its products with new features and functionality to address any issues that might impact the data on your SAN.

Encryption is a tool that can be used to protect the confidentiality of the information in the enterprise. To understand if and how an encryption solution should be deployed, administrators need to understand and assess the risks of unauthorized access and disclosure at each point of the information flow. They must also understand how deployment of encryption technology may add risk to other areas of the business, including complexity added to management, and risks to availability of encrypted data to authorized users. Data unavailability can come from something as simple as key management, which is perhaps the most important factor to consider in implementing an encryption solution. Encryption should be considered as part of a total security solution, but not the only solution; administrators need to take advantage of protection options at all levels of the information flow and architecture. Two general issues that are present across encryption implementations are:

- The conversion of plaintext to ciphertext when encrypting data for the first time or ciphertext to ciphertext when encrypting with a new key. Both are done as a data migration project, even when it is done in place. Host resources, impact to CPU utilization, and running applications must be considered.
- The replication of encrypted data across the WAN. Encryption, if done correctly, produces random, uncompressible data that will impact the utilization of remote connectivity.

Table e51.2 summarizes the various deployment options.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The

TABLE e51.2 Summary of Encryption Approaches.

	Encryption	Key Management	Backup	Issues	Risks Addressed
Application	Typically done in software but can be done in hardware.	Typically stored in memory or file. Coordination of keys across applications presents challenges to sharing information. Needs external appliance to meet FIPS 140-2 Level 3	Peer process to the application and will back up encrypted data. No compression. Lifetime key management challenges.	Encryption can be host system intensive and is a per-application process. If more than one application is used on a host, sharing of information can be an issue. Storing keys for lifetime of data can also be an issue for application upgrades. Can impact ediscovery.	Protects against operating system and network attacks as well as media theft.
Host	Typically done in software but can be done in hardware. Can be file or block based.	Typically stored in memory but can have external appliance.	Peer process will back up data and host will need to re-encrypt.	Encryption can be host system intensive. Storing keys for lifetime of data can also be an issue for OS upgrades (if external key management facility is not used). Can impact ediscovery.	Protects against network attacks as well as media theft.
Network	Typically done in hardware.	Managed for the lifetime of data in hardware.	Can perform block-based encryption to disk or tape or file-based encryption. Can also incorporate compression for tape backup or coordination for replication.	A single aggregation point in the network for encryption can be a performance bottleneck.	Protects against some network attacks as well as media theft.
Disk based	Typically done in hardware but can be done in software.	Can be done per disk or LUN. Key management can be resident-to-array or leveraged from external appliance.	Always presents unencrypted data external to disk.	Handles very focused use case. Largest exposure of encrypted data in an enterprise.	Protects against media theft.

answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? As with any IT subsystem, implementing the appropriate level of security for storage area networks (SANs) depends on few factors.
2. True or False? Not every company has its own organizational structures and security requirements.
3. True or False? Authentication, authorization, and accounting (AAA) is a term for a framework for intelligently controlling access to computer resources, enforcing policies, auditing usage, and providing the information necessary to bill for services.
4. True or False? The second step in developing adequate datacenter controls is to know what the controls need to address—for example, the vulnerabilities that can be exploited.
5. True or False? Fabric security augments overall application security.

Multiple Choice

1. Secure access to management services is known as:
   A. SAN management access
   B. Location technology
   C. Promotional email
   D. Malformed request DoS
   E. Data controller
2. Secure device access to fabric service is known as:
   A. Fabric access
   B. Location technology
   C. Valid
   D. Load-Based DoS
   E. Bait

3. Secure access to targets and Logical Unit Numbers (LUNs) is known as:
   - **A.** Data minimization
   - **B.** XACML
   - **C.** Target access
   - **D.** Strong narrative

Storage Area Networking Security Devices

Robert Rounsavall
Terremark Worldwide, Inc.

Storage area networking (SAN) devices have become a critical IT component of almost every business today. The upside and intended consequences of using a SAN are to consolidate corporate data as well as reduce cost, complexity, and risks. The tradeoff and downside to implementing SAN technology are that the risks of large-scale data loss are higher in terms of both cost and reputation. With the rapid adoption of virtualization, SANs now house more than just data; they house entire virtual servers and huge clusters of servers in "enterprise clouds."[1] In addition to all the technical, management, deployment, and protection challenges, a SAN comes with a full range of legal regulations such as PCI, HIPAA, SOX, GLBA, SB1386, and many others. Companies keep their informational "crown jewels" on their SANs but in most cases do not understand all the architecture issues and risks involved, which can cost an organization huge losses. This chapter covers all the issues and security concerns related to storage area network security.

1. WHAT IS A SAN?

The Storage Network Industry Association (SNIA)[2] defines a SAN as a data storage system consisting of various storage elements, storage devices, computer systems, and/or appliances, plus all the control software, all communicating in efficient harmony over a network. Put in simple terms, a SAN is a specialized, high-speed network attaching servers and storage devices and, for this reason, it is sometimes referred to as "the network behind the servers." A SAN allows "any-to-any" connections across the network, using interconnected elements such as routers, gateways, hubs, switches, and directors. It eliminates the traditional dedicated connection between a server and storage as well as the concept that the server effectively "owns and manages" the storage devices. It also eliminates any restriction to the amount of data that a server can access, currently limited by the number of storage devices attached to the individual server. Instead, a SAN introduces the flexibility of networking to enable one server or many heterogeneous servers to share a common storage utility, which may comprise many storage devices, including disk, tape, and optical storage. Additionally, the storage utility may be located far from the servers that use it.

The SAN can be viewed as an extension to the storage bus concept, which enables storage devices and servers to be interconnected using similar elements to those used in local area networks (LANs) and wide area networks (WANs). SANs can be interconnected with routers, hubs, switches, directors, and gateways. A SAN can also be shared between servers and/or dedicated to one server. It can be local or extended over geographical distances.

2. SAN DEPLOYMENT JUSTIFICATIONS

Perhaps a main reason SANs have emerged as the leading advanced storage option is because they can often alleviate many if not all the data storage "pain points" of IT managers.[3] For quite some time IT managers have been in a predicament in which some servers, such as database servers, run out of hard disk space rather quickly, whereas other servers, such as application servers, tend to not need a whole lot of disk space and usually have storage to spare. When a SAN is implemented, the storage can be spread throughout servers on an as-needed basis. The following are further justifications and benefits for implementing a storage area network:

- They allow for more manageable, scalable, and efficient deployment of mission-critical data.

1. The Enterprise Cloud by Terremark, www.theenterprisecloud.com.
2. Storage Network Industry Association, www.snia.org/home.
3. SAN justifications: http://voicendata.ciol.com/content/enterprise_zone/105041303.asp.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00052-0

- SAN designs can protect resource investments from unexpected turns in the economic environment and changes in market adoption of new technology.
- SANs help with the difficulty of managing large, disparate islands of storage from multiple physical and virtual locations.
- SANs reduce the complexity of maintaining scheduled backups for multiple systems and difficulty in preparing for unscheduled system outages.
- The inability to share storage resources and achieve efficient levels of subsystem utilization is avoided.
- SANs help address the issue of a shortage of qualified storage professionals to manage storage resources effectively.
- SANs help us understand how to implement the plethora of storage technology alternatives, including appropriate deployment of Fibre Channel as well as Internet small computer systems interface (iSCSI), Fibre Channel over IP (FCIP), and InfiniBand.
- SANs allow us to work with restricted budgets and increasing costs of deploying and maintaining them, despite decreasing prices for physical storage in terms of average street price per terabyte.

In addition to all these benefits, the true advantage of implementing a SAN is that it enables the management of huge quantities of email and other business-critical data such as that created by many enterprise applications, such as customer relationship management (CRM), enterprise resource planning (ERP), and others. The popularity of these enterprise applications, regulatory compliance, and other audit requirements have resulted in an explosion of information and data that have become the lifeblood of these organizations, greatly elevating the importance of a sound storage strategy. Selecting a unified architecture that integrates the appropriate technologies to meet user requirements across a range of applications is central to ensuring storage support for mission-critical applications. Then matching technologies to user demands allows for optimized storage architecture, providing the best use of capital and IT resources.

A large number of enterprises have already implemented production SANs, and many industry analysts have researched the actual benefits of these implementations. A Gartner[4] study of large enterprise data center managers shows that 64% of those surveyed were either running or deploying a SAN. Another study by the Aberdeen Group cites that nearly 60% of organizations that have SANs installed have two or more separate SANs. The study also states that 80% of those surveyed felt that they had satisfactorily achieved their main goals for implementing a SAN. Across the board, all vendor case studies and all industry analyst investigations have found the following core benefits of SAN implementation compared to a direct attached storage (DAS) environment:

- Ease of management
- Increased subsystem utilization
- Reduction in backup expense
- Lower Total Cost of Ownership (TCO)

3. THE CRITICAL REASONS FOR SAN SECURITY

SAN security is important because there is more concentrated, centralized, high-value data at risk than in normal distributed servers with built-in, smaller-scale storage solutions. On a SAN you have data from multiple devices and multiple parts of the network shared on one platform. This typically fast-growing data can be consolidated and centralized from locations all over the world. SANs also store more than just data; with the increasing acceptance of server virtualization, multiple OS images and the data they create are being retrieved from and enabled by SANs.

Why is SAN Security Important?

Some large-scale security losses have occurred by intercepting information incrementally over time, but the vast majority of breaches involve access or loss of data from the corporate SAN. (For deeper insight into the numbers, check out the Data Loss Web site. This website tracks incidents and is a clearinghouse of data loss each month.[5])

A wide range of adversaries can attack an organization simply to access its SAN, which is where all the company data rests. Common adversaries who will be looking to access the organization's main data store are:

- Financially motivated attackers and competitors
- Identity thieves
- Criminal gangs
- State-sponsored attackers
- Internal employees
- Curious business partners

If one or some of these perpetrators were to be successful in stealing or compromising the data in the SAN, and if news got around that your customer data had been compromised, it could directly impact your organization monetarily and cause significant losses in terms of:

- Reputation
- Time lost
- Forensics investigations

4. Gartner, www.gartner.com.

5. Data Loss Database, http://datalossdb.org/.

- Overtime for IT
- Business litigation
- Perhaps even a loss of competitive edge—for example, if the organization's proprietary manufacturing process is found in the wild

4. SAN ARCHITECTURE AND COMPONENTS

In its simplest form, a SAN is a number of servers attached to a storage array using a switch. Figure 52.1 is a diagram of all the components involved.

SAN Switches

Specialized switches called SAN switches are at the heart of a typical SAN. Switches provide capabilities to match the number of host SAN connections to the number of connections provided by the storage array. Switches also provide path redundancy in the event of a path failure from host server to switch or from storage array to switch. SAN switches can connect both servers and storage devices and thus provide the connection points for the fabric of the SAN. For smaller SANs, the standard SAN switches are called *modular switches* and can typically support eight or 16 ports (though some 32-port modular switches are beginning to emerge). Sometimes modular switches are interconnected to create a fault-tolerant fabric. For larger SAN fabrics, director-class switches provide a larger port capacity (64 to 128 ports per switch) and built-in fault tolerance. The type of SAN switch, its design features, and its port capacity all contribute to its overall capacity, performance, and fault tolerance. The number of switches, types of switches, and manner in which the switches are interconnected define the topology of the fabric.

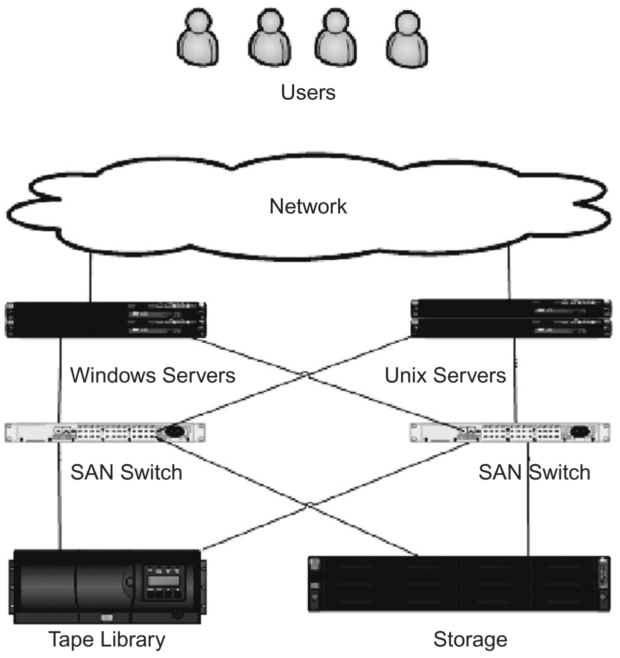

FIGURE 52.1 Simple SAN elements.

Network Attached Storage (NAS)

Network attached storage (NAS) is file-level data storage providing data access to many different network clients. The Business Continuity Planning (BCP) defined in this category address the security associated with file-level storage systems/ecosystems. They cover the Network File System (NFS), which is often used by Unix and Linux (and their derivatives') clients as well as SMB/CIFS, which is frequently used by Windows clients.

Fabric

When one or more SAN switches are connected, *a fabric* is created. The fabric is the actual network portion of the SAN. Special communications protocols such as Fibre Channel (FC), iSCSI, and Fibre Channel over Ethernet (FCoE) are used to communicate over the entire network. Multiple fabrics may be interconnected in a single SAN, and even for a simple SAN it is not unusual for it to be composed of two fabrics for redundancy.

HBA and Controllers

Host servers and storage systems are connected to the SAN fabric through ports in the fabric. A host connects to a fabric port through a Host Bus Adapter (HBA), and the storage devices connect to fabric ports through their controllers. Each server may host numerous applications that require dedicated storage for applications processing. Servers need not be homogeneous within the SAN environment.

Tape Library

A tape library is a storage device that is designed to hold, manage, label, and store data to tape. Its main benefit is related to cost/TB, but its slow random access relegates it to an archival device.

Protocols, Storage Formats and Communications

The following protocols and file systems are other important components of a SAN.

Block-Based IP Storage (IP)

Block-based IP storage is implemented using protocols such as iSCSI. This also includes Internet Fibre Channel Protocol (iFCP) and FCIP to transmit SCSI commands over IP networks.

Secure iSCSI

Internet SCSI or iSCSI, which is described in IETF RFC 3720, is a connection-oriented command/response protocol that runs over TCP. It is also used to access disk, tape, and other devices.

Secure FCIP

Fibre Channel over TCP/IP (FCIP), defined in IETF RFC 3821, is a pure Fibre Channel encapsulation protocol. It allows the interconnection of islands of Fibre Channel storage area networks through IP-based networks to form a unified storage area network.

Fibre Channel Storage (FCS)

Fibre Channel is a gigabit-speed network technology used for block-based storage. The Fibre Channel Protocol (FCP) is the interface protocol used to transmit SCSI on this network technology.

Secure FCP

Fibre Channel entities (host bus adapters or HBAs, switches, and storage) can contribute to the overall secure posture of a storage network. This is done by employing mechanisms such as filtering and authentication.

Secure Fibre Channel Storage Networks

A SAN is architected to attach remote computer storage devices (such as disk arrays, tape libraries, and optical jukeboxes) to servers in such a way that, to the operating system, the devices appear as though they're locally attached. These SANs are often based on a Fibre Channel fabric topology that utilizes the Fibre Channel Protocol (FCP).

SMB/CIFS

SMB/CIFS is a network protocol whose most common use is sharing files. This is especially true in Microsoft operating system environments.

Network File System (NFS)

NFS is a client/server application, communicating with a remote procedure call (RPC)-based protocol. It enables file systems physically residing on one computer system or NAS device to be used by other computers in the network, appearing to users on the remote host as just another local disk.

Online Fixed Content

An online fixed content system usually contains at least some data subject to retention policies and a retention-managed storage system/ecosystem is commonly used for such data.

5. SAN GENERAL THREATS AND ISSUES

A SAN is a prime target of all attackers due to the goldmine of information that can be attained by accessing it. Here we discuss the general threats and issues related to SANs.

SAN Cost: A Deterrent to Attackers

Unlike many network components such as servers, routers, and switches, SANs are quite expensive, which does raise the bar for attackers a little bit. There are not huge numbers of people with SAN protocol expertise, and not too many people have a SAN in their home lab, unless they are a foreign government that has dedicated resources to researching and exploiting these types of vulnerabilities. Why would anyone go to the trouble when it would be much easier to compromise the machines of the people who manage the SANs or the servers that are themselves connected to the SAN?

The barrier to entry to directly attack the SAN is high; however, the ability to attack the management tools and administrators who access the SAN is not. Most are administered via Web interfaces, software applications, or command-line interfaces. An attacker simply has to gain root or administrator access on those machines to be able to attack the SAN.

Physical Level Threats, Issues, and Risk Mitigation

There can be many physical risks involved in using a SAN. It is important to take them all into consideration when planning and investing in a storage area network:

- Locate the SAN in a secure datacenter
- Ensure that proper access controls are in place
- Cabinets, servers, and tape libraries come with locks; use them
- Periodically audit the access control list
- Verify whether former employees can access the location where the SAN is located
- Perform physical penetration and social engineering tests on a regular basis

Physical Environment

The SAN must be located in an area with proper ventilation and cooling. Ensure that your datacenter has proper

cooling and verify any service-level agreements with a third-party provider with regard to power and cooling.

Hardware Failure Considerations

Ensure that the SAN is designed and constructed in such a way that when a piece of hardware fails, it does not cause an outage. Schedule failover testing on a regular basis during maintenance windows so that it will be completed on time.

Secure Sensitive Data on Removable Media to Protect "Externalized Data"

Many of the data breaches that fill the newspapers and create significant embarrassments for organizations are easily preventable and involve loss of *externalized data* such as backup media. To follow are some ideas to avoid unauthorized disclosure while data is in transit:

- Offsite backup tapes of sensitive or regulated data should be encrypted as a general practice and must be encrypted when leaving the direct control of the organization; encryption keys must be stored separately from data.
- Use only secure and bonded shippers if not encrypted. (Remember that duty-of-care contractual provisions often contain a limitation of liability limited to the bond value. The risk transfer value is often less than the data value.)
- Secure sensitive data transferred between datacenters.
- Sensitive/regulated data transferred to and from remote datacenters must be encrypted in flight.
- Secure sensitive data in third-party datacenters.
- Sensitive/regulated data stored in third-party datacenters must be encrypted prior to arrival (both in-flight and at-rest).
- Secure your data being used by ediscovery tools.

Know Thy Network (or Storage Network)

It is not only a best practice but critical that the SAN is well documented. All assets must be known. All physical and logical interfaces must be known. Create detailed physical and logical diagrams of the SAN. Identify *all* interfaces on the SAN gear. Many times people overlook the network interfaces for the out-of-band management. Some vendors put a sticker with login and password physically on the server for the out-of-band management ports. Ensure that these are changed. Know what networks can access the SAN and from where. Verify all entry points and exit points for data, especially sensitive data such as financial information or PII. If an auditor asks, it should be simple to point to exactly where that data rests and where it goes on the network.

Use Best Practices for Disaster Recovery and Backup

Guidelines such as the NIST Special Publication 800-34[6] outline best practices for disaster recovery and backup. The seven steps for contingency planning are outlined below:

1. *Develop the contingency planning policy statement.* A formal department or agency policy provides the authority and guidance necessary to develop an effective contingency plan.
2. *Conduct the business impact analysis (BIA).* The BIA helps identify and prioritize critical IT systems and components. A template for developing the BIA is also provided to assist the user.
3. *Identify preventive controls.* Measures taken to reduce the effects of system disruptions can increase system availability and reduce contingency life-cycle costs.
4. *Develop recovery strategies.* Thorough recovery strategies ensure that the system may be recovered quickly and effectively following a disruption.
5. *Develop an IT contingency plan.* The contingency plan should contain detailed guidance and procedures for restoring a damaged system.
6. *Plan testing, training, and exercises.* Testing the plan identifies planning gaps, whereas training prepares recovery personnel for plan activation; both activities improve plan effectiveness and overall agency preparedness.
7. *Plan maintenance.* The plan should be a living document that is updated regularly to remain current with system enhancements.

Logical Level Threats, Vulnerabilities, and Risk Mitigation

Aside from the physical risks and issues with SANs, there are also many logical threats. A threat is defined as any potential danger to information or systems. These are the same threats that exist in any network and they are also applicable to a storage network because Windows and Unix servers are used to access and manage the SAN. For this reason, it is important to take a defense-in-depth approach to securing the SAN. Some of the threats that face a SAN are as follows:

- *Internal threats (malicious).* A malicious employee could access the sensitive data in a SAN via management interface or poorly secured servers.
- *Internal threats (nonmalicious).* Not following proper procedure such as using change management could

6. NIST Special Publication 800-34, http://csrc.nist.gov/publications/nistpubs/800-34/sp800-34.pdf.

bring down a SAN. A misconfiguration could bring down a SAN. Poor planning for growth could limit your SAN.
- *Outside threats.* An attacker could access your SAN data or management interface by compromising a management server, a workstation or laptop owned by an engineer, or other server that has access to the SAN.

The following parts of the chapter deal with protecting against these threats.

Begin with a Security Policy

Having a corporate information security policy is essential.[7] Companies should already have such policies, and they should be periodically reviewed and updated. If organizations process credit cards for payment and are subject to the Payment Card Industry (PCI)[8] standards, they are mandated to have a security policy. Federal agencies subject to certification and accreditation under guidelines such as DIACAP[9] must also have security policies.

Is storage covered in the corporate security policy? Some considerations for storage security policies include the following:

- Identification and classification of sensitive data such as PII, financial, trade secrets, and business-critical data
- Data retention, destruction, deduplication, and sanitization
- User access and authorization

Instrument the Network with Security Tools

Many of the network security instrumentation devices such as IDS/IPS have become a commodity, required for compliance and a minimum baseline for any IT network. The problem with many of those tools is that they are signature based and only provide alerts and packet captures on the offending packet alerts. Adding tools such as full packet capture and network anomaly detection systems can allow a corporation to see attacks that are not yet known. They can also find attacks that bypass the IDS/IPSs and help prove to customers and government regulators whether or not the valuable data was actually stolen from the network.

7. Information Security Policy Made Easy, www.informationshield.

8. PCI Security Standards, https://www.pcisecuritystandards.org/.

9. DIACAP Certification and Accreditation standard, http://iase.disa.mil/ditscap/ditscap-to-diacap.html.

Intrusion Detection and Prevention Systems (IDS/IPS)

Intrusion detection and prevention systems can detect and block attacks on a network. Intrusion prevention systems are usually inline and can block attacks. A few warnings about IPS devices:

- Their number-one goal is to *not* bring down the network.
- Their number-two goal is to not block legitimate traffic.

Time after time attacks can slip by these systems. They will block the low-hanging fruit, but a sophisticated attacker can trivially bypass IDS/IPS devices. Commercial tools include TippingPoint, Sourcefire, ISS, and Fortinet. Open-source tools include Snort and Bro.

Network Traffic Pattern Behavior Analysis

Intrusion detection systems and vulnerability-scanning systems are only able to detect well-known vulnerabilities. A majority of enterprises have these systems as well as log aggregation systems but are unable to detect 0-day threats and other previously compromised machines. The answer to this problem is NetFlow data. NetFlow data shows all connections into and out of the network. There are commercial and open-source tools. Commercial tools are Arbor Networks and Mazu Networks. Open-source tools include nfdump and Argus.

Full Network Traffic Capture and Replay

Full packet capture tools allow security engineers to record and play back all the traffic on the network. This allows for validation of IDS/IPS alerts and validation of items that NetFlow or log data is showing. Commercial tools include Niksun, NetWitness, and NetScout. Open-source tools include Wireshark and tcpdump.

Secure Network and Management tools

It is important to secure the network and management tools. If physical separation is not possible, then at a very minimum logical separation must occur. For example:

- Separate the management network with a firewall.
- Ensure user space and management interfaces are on different subnets/VLANs.
- Use strong communication protocols such as SSH, SSL, and VPNs to connect to and communicate with the management interfaces.
- Avoid using out-of-band modems if possible. If absolutely necessary, use the callback feature on the modems.

- Have a local technician or datacenter operators connect the line only when remote dial-in access is needed, and then disconnect when done.
- Log all external maintenance access.

Restrict Remote Support

Best practice is to not allow remote support; however, most SANs have a “call home” feature that allows them to call back to the manufacturer for support. Managed network and security services are commonplace. If remote access for vendors is mandatory, take extreme care. Here are some things that can help make access to the SAN safe:

- Disable the remote “call home” feature in the SAN until needed.
- Do not open a port in the firewall and give direct external access to the SAN management station.
- If outsourcing management of a device, ensure that there is a VPN set up and verify that the data is transmitted encrypted.
- On mission-critical systems, do not allow external connections. Have internal engineers connect to the systems and use a tool such as WebEx or GoToAssist to allow the vendor to view while the trusted engineer controls the mouse and keyboard.

Attempt to Minimize User Error

It is not uncommon for a misconfiguration to cause a major outage. Not following proper procedure can cause major problems. Not all compromises are due to malicious behaviors; some may be due to mistakes made by trusted personnel.

Establish Proper Patch Management Procedures

Corporations today are struggling to keep up with all the vulnerabilities and patches for all the platforms they manage. With all the different technologies and operating systems it can be a daunting task. Mission-critical storage management gear and network gear cannot be patched on a whim whenever the administrator feels like it. There are Web sites dedicated to patch management software. Microsoft Windows Software Update Services (WSUS) is a free tool that only works with Windows. Other commercial tools can assist with cross-platform patch management deployment and automation:

- Schedule updates.
- Live within the change window.
- Establish a rollback procedure.
- Test patches in a lab if at all possible. Use virtual servers if possible, to save cost.
- Purchase identical lab gear if possible. Many vendors will sell “nonproduction” lab gear at more than 50% discount. This allows for test scenarios and patching in a nonproduction environment without rolling into production.
- After applying patches or firmware, validate to make sure that the equipment was actually correctly updated.

Use Configuration Management Tools

Many large organizations have invested large amounts of money in network and software configuration management tools to manage hundreds or thousands of devices around the network. These tools store network device and software configurations in a database format and allow for robust configuration management capabilities. An example is HP’s Network Automation System,[10] which can do the following:

- Reduce costs by automating time-consuming manual compliance checks and configuration tasks.
- Pass audit and compliance requirements easily with proactive policy enforcement and out-of-the-box audit and compliance reports (IT Infrastructure Library (ITIL), Cardholder Information Security Program (CISP), HIPAA, SOX, GLBA, and others).
- Improve network security by recognizing and fixing security vulnerabilities before they affect the network, using an integrated security alert service.
- Increase network stability and uptime by preventing the inconsistencies and misconfigurations that are at the root of most problems.
- Use process-powered automation to deliver application integrations, which deliver full IT life-cycle workflow automation without scripting.
- Support SNMPv3 and IPv6, including dual-stack IPv4 and IPv6 support. HP Network Automation supports both of these technologies to provide flexibility in your protocol strategy and implementation.
- Use automated software image management to deploy wide-scale image updates quickly with audit and rollback capabilities.

Set Baseline Configurations

If a commercial tool is not available, there are still steps that can be taken. Use templates such as the ones provided by the Center for Internet Security or the National Security Agency. They offer security templates for multiple operating systems, software packages, and network

10. HP Network Automation System, https://h10078.www1.hp.com/cda/hpms/display/main/hpms_content.jsp?zn = bto&cp = 1-11-271-273_4000_100_.

devices. They are free of charge and can be modified to fit the needs of the organization. In addition:

- Create a base configuration for all production devices.
- Check with the vendor to see if they have baseline security guides. Many of them do internally and will provide them on request.
- Audit the baseline configurations.
- Script and automate as much as possible.

Center for Internet Security[11]

The Center for Internet Security (CIS) is a not-for-profit organization that helps enterprises reduce the risk of business and ecommerce disruptions resulting from inadequate technical security controls and provides enterprises with resources for measuring information security status and making rational security investment decisions.

National Security Agency[12]

NSA initiatives in enhancing software security cover both proprietary and open-source software, and we have successfully used both proprietary and open-source models in our research activities. NSA's work to enhance the security of software is motivated by one simple consideration: Use our resources as efficiently as possible to give NSA's customers the best possible security options in the most widely employed products. The objective of the NSA research program is to develop technologic advances that can be shared with the software development community through a variety of transfer mechanisms. The NSA does not favor or promote any specific software product or business model. Rather, it promotes enhanced security.

Vulnerability Scanning

PCI requirements include both internal and external vulnerability scanning. An area that is commonly overlooked when performing vulnerability scans is the proprietary devices and appliances that manage the SAN and network. Many of these have Web interfaces and run Web applications on board. Vulnerability-scanning considerations are as follows:

- Use the Change Management/Change Control process to schedule the scans. Even trained security professionals who are good at not causing network problems sometimes cause network problems.
- Know exactly what will be scanned.
- Perform both internal and external vulnerability scans.
- Scan the Web application and appliances that manage the SAN and the network.
- Use more than one tool to scan.
- Document results and define metrics to know whether vulnerabilities are increasing or decreasing.
- Set up a scanning routine and scan regularly with updated tools.

System Hardening

System hardening is an important part of SAN security. Hardening includes all the SAN devices and any machines that connect to it as well as management tools. There are multiple organizations that provide hardening guides for free that can be used as a baseline and modified to fit the needs of the organization:

- Do not use shared accounts. If all engineers use the same account, there is no way to determine who logged in and when.
- Remove manufacturers' default passwords.
- If supported, use central authentication such as RADIUS.
- Use the principle of least privilege. Do not give all users on the device administrative credentials unless they absolutely need them. A user just working on storage does not need the ability to reconfigure the SAN switch.

Management Tools

It is common for management applications to have vulnerabilities that the vendor will refuse to fix or deny that they are vulnerabilities. They usually surface after a vulnerability scan or penetration test. When vulnerabilities are found, there are steps that can be taken to mitigate the risk:

- Contact the vendor regardless. The vendor needs to know that there are vulnerabilities and they should correct them.
- Verify if they have a hardening guide or any steps that can be taken to mitigate the risk.
- Physically or logically segregate the tools and apply strict ACLs or firewall rules.
- Place it behind an intrusion prevention device.
- Place behind a Web application firewall, if a Web application.
- Audit and log access very closely.
- Set up alerts for logins that occur outside normal hours.
- Use strong authentication if available.
- Review the logs.

Separate Areas of the SAN

In the world of security, a defense-in-depth strategy is often employed with an objective of aligning the security

11. Center for Internet Security, www.cisecurity.org.
12. National Security Agency security templates, www.nsa.gov/snac/index.cfm.

measures with the risks involved. This means that there must be security controls implemented at each layer that may create an exposure to the SAN system. Most organizations are motivated to protect sensitive (and business/mission-critical) data, which typically represents a small fraction of the total data. This narrow focus on the most important data can be leveraged as the starting point for data classification and a way to prioritize protection activities. The best way to be sure that there is a layered approach to security is to address each aspect of a SAN one by one and determine the best strategy to implement physical, logical, virtual, and access controls.

Physical

Segregating the production of some systems from other system classes is crucial to proper data classification and security. For example, if it is possible to physically segregate the quality assurance data from the research and development data, there is a smaller likelihood of data leakage between departments and therefore out to the rest of the world.

Logical

When a SAN is implemented, segregating storage traffic from normal server traffic is quite important because there is no need for the data to travel on the same switches as your end users browsing the Internet, for example. Logical Unit Numbers (LUN) Masking, Fibre Channel Zoning, and IP VLANs can assist in separating data.

Virtual

One of the most prevalent uses recently for storage area networks is the storing of full-blown virtual machines that run from the SAN itself. With this newest of uses for SANs, the movement of virtual servers from one data store to another is something that is required in many scenarios and one that should be studied to identify potential risks.

Penetration Testing

Penetration testing like vulnerability scanning is becoming a regulatory requirement. Now people can go to jail for losing data and not complying with these regulations. Penetration-testing the SAN may be difficult due to the high cost of entry, as noted earlier. Most people don't have a SAN in their lab to practice pen testing.

Environments with custom applications and devices can be sensitive to heavy scans and attacks. Inexperienced people could inadvertently bring down critical systems. The security engineers who have experience working in these environments choose tools depending on the environment. They also tread lightly so that critical systems are not brought down. Boutique security firms might not have $100k to purchase a SAN so that their professional services personnel can do penetration tests on SANs. With the lack of skilled SAN technicians currently in the field, it is not likely that SAN engineers will be rapidly moving into the security arena. Depending on the size of the organization, there are things that can be done to facilitate successful penetration testing. An internal penetration testing team does the following:

- Have personnel cross-train and certify on the SAN platform in use.
- Provide the team access to the lab and establish a regular procedure to perform a pen test.
- Have a member of the SAN group as part of the pentest team.
- Follow practices such as the OWASP guide for Web application testing and the OSSTMM for penetration-testing methodologies.

OWASP

The Open Web Application Security Project (OWASP; www.owasp.org) is a worldwide free and open community focused on improving the security of application software. Our mission is to make application security "visible" so that people and organizations can make informed decisions about application security risks.

OSSTMM

The Open Source Security Testing Methodology Manual (OSSTMM; www.isecom.org/osstmm/) is a peer-reviewed methodology for performing security tests and metrics. The OSSTMM test cases are divided into five channels (sections), which collectively test information and data controls, personnel security awareness levels, fraud and social engineering control levels, computer and telecommunications networks, wireless devices, mobile devices, physical security access controls, security processes, and physical locations such as buildings, perimeters, and military bases. The external penetration testing team does the following:

- Validates SAN testing experience through references and certification
- Avoids firms that do not have access to SAN storage gear
- Asks to see a sanitized report of a previous penetration test that included a SAN

Whether an internal or external penetration-testing group, it is a good idea to belong to one of the professional security associations in the area, such as the Information Systems Security Association (ISSA) or

Information Systems Audit and Control Association (ISACA).

ISSA

ISSA (www.issa.org) is a not-for-profit, international organization of information security professionals and practitioners. It provides educational forums, publications, and peer interaction opportunities that enhance the knowledge, skill, and professional growth of its members.

ISACA

ISACA (www.isaca.org) got its start in 1967 when a small group of individuals with similar jobs—auditing controls in the computer systems that were becoming increasingly critical to the operations of their organizations—sat down to discuss the need for a centralized source of information and guidance in the field. In 1969 the group formalized, incorporating as the EDP Auditors Association. In 1976 the association formed an education foundation to undertake large-scale research efforts to expand the knowledge and value of the IT governance and control field.

Encryption

Encryption is the conversion of data into a form called *ciphertext* that cannot be easily understood by unauthorized people. *Decryption* is the process of converting encrypted data back into its original form so that it can be understood.

Confidentiality

Confidentiality is the property whereby information is not disclosed to unauthorized parties. *Secrecy* is a term that is often used synonymously with confidentiality. Confidentiality is achieved using encryption to render the information unintelligible except by authorized entities.

The information may become intelligible again by using decryption. For encryption to provide confidentiality, the cryptographic algorithm and mode of operation must be designed and implemented so that an unauthorized party cannot determine the secret or private keys associated with the encryption or be able to derive the plaintext directly without deriving any keys.[13]

Data encryption can save a company time, money, and embarrassment. There are countless examples of lost and stolen media, especially hard drives and tape drives. A misplacement or theft can cause major headaches for an organization. Take, for example, the University of Miami[14]:

A private off-site storage company used by the University of Miami has notified the University that a container carrying computer back-up tapes of patient information was stolen. The tapes were in a transport case that was stolen from a vehicle contracted by the storage company on March 17 in downtown Coral Gables, the company reported. Law enforcement is investigating the incident as one of a series of petty thefts in the area.

Shortly after learning of the incident, the University determined it would be unlikely that a thief would be able to access the back-up tapes because of the complex and proprietary format in which they were written. Even so, the University engaged leading computer security experts at Terremark Worldwide[15] to independently ascertain the feasibility of accessing and extracting data from a similar set of back-up tapes.

Anyone who has been a patient of a University of Miami physician or visited a UM facility since January 1, 1999, is likely included on the tapes. The data included names, addresses, Social Security numbers, or health information. The University will be notifying by mail the 47,000 patients whose data may have included credit card or other financial information regarding bill payment.

Even thought it was unlikely that the person who stole the tapes had access to the data or could read the data, the university still had to notify 47,000 people that their data may have been compromised. Had the tape drives been encrypted, they would not have been in the news at all and no one would have had to worry about personal data being compromised.

Deciding What to Encrypt

Deciding what type of data to encrypt (see checklist, "An Agenda For Action For The Encryption Of Data") and how best to do it can be a challenge. It depends on the type of data that is stored on the SAN. Encrypt backup tapes as well.

Many of the vendors implement encryption in different ways. NIST SP 800-57 contains best practices for key management and information about various cryptographic ciphers. The following are the recommended minimum symmetric security levels, defined as bits of strength (not key size):

- 80 bits of security until 2010 (128-bit AES and 1024-bit RSA)
- 112 bits of security through 2030 (3DES, 128-AES and 2048-bit RSA)
- 128 bits of security beyond 2030 (128-AES and 3072-bit RSA)

An Agenda for Action for the Encryption of Data

There are two main types of encryption to focus on: data in transit and data at rest. SNIA put out a white paper called *Encryption of Data At-Rest: Step-by-Step Checklist,* which outlines nine steps for encrypting data at rest[16] (Check All Tasks Completed):

_____**1.** Understand confidentiality drivers.
_____**2.** Classify the data assets.
_____**3.** Inventory data assets.
_____**4.** Perform data flow analysis.
_____**5.** Determine the appropriate points of encryption.
_____**6.** Design encryption solution.
_____**7.** Begin data realignment.
_____**8.** Implement solution.
_____**9.** Activate encryption.

FIGURE 52.2 Notice the clear, legible text on the right.

Type of Encryption to Use

The type of encryption used should contain a strong algorithm and be publicly known. Algorithms such as ASE, RSA, SHA, and Twofish are known and tested. All the aforementioned encryption algorithms have been tested and proven to be strong if properly implemented. Organizations should be wary of vendors saying that they have their own "unknown" encryption algorithm. Many times it is just data compression or a weak algorithm that the vendor wrote by itself. Though it sounds good in theory, the thousands of mathematicians employed by the NSA spend years and loads of computer power trying to break well-known encryption algorithms.

Proving that Data is Encrypted

A well-architected encryption plan should be transparent to the end user of the data. The only way to know for sure that the data is encrypted is to verify the data. Data at rest can be verified using forensic tools such as dd for Unix or the free FTK[17] imager for Windows. Data in transit can be verified by network monitoring tools such as Wireshark.

Turn on event logging for any encryption hardware or software. Make sure it is logging when it turns on or off. Have a documented way to verify that the encryption was turned on while it had the sensitive data on the system (see Figure 52.2).

Encryption Challenges and Other Issues

No method of defense is perfect. Human error and computer vulnerabilities do pose encryption challenges (see Figure 52.3). A large financial firm had personal information on its network, including 34,000 credit cards with names and account numbers. The network administrator had left the decryption key on the server. After targeting the server for a year and a half, the attacker was able to get the decryption key and finally able to directly query the fully encrypted database and pull out 34,000 cards.

Logging

Logging is an important consideration when it comes to SAN security. There are all sorts of events that can be logged. When a security incident happens, having proper

FIGURE 52.3 Notice Encrypted Data on the right-hand side.

log information can mean the difference between solving the problem and not knowing whether your data was compromised. NIST has an excellent guide to Security Log Management. The SANS Institute has a guide on the top five most essential log reports.

There are multiple commercial vendors as well as open-source products for log management. Log management has evolved from standalone syslog servers to complex architectures for Security Event/Information Management. Acronyms used for these blend together as SEM, SIM, and SEIM. In addition to log data, they can take in data from IDSs, vulnerability assessment products, and many other security tools to centralize and speed up the analysis and processing of huge amounts of logs. More of a difference is being made between Security Event Management and audit logging. The former is geared toward looking at events of interest on which to take action; the latter is geared to compliance. In today's legal and compliance environment an auditor will ask an enterprise to immediately provide logs for a particular device for a time period such as the previous 90 days. With a solid log management infrastructure, this request becomes trivial and a powerful tool to help solve problems. NIST Special Publication 800-92[18] makes the following recommendations:

- Organizations should establish policies and procedures for log management.
- Organizations should prioritize log management appropriately throughout the organization.
- Organizations should create and maintain a log management infrastructure.
- Organizations should provide proper support for all staff with log management responsibilities.
- Organizations should establish standard log management operational processes.

18. NIST SP 800-92 http://csrc.nist.gov/publications/nistpubs/800-92/SP800-92.pdf.

Policies and Procedures

To establish and maintain successful log management activities, an organization should develop standard processes for performing log management. As part of the planning process, an organization should define its logging requirements and goals.

Prioritize Log Management

After an organization defines its requirements and goals for the log management process, it should then prioritize the requirements and goals based on the organization's perceived reduction of risk and the expected time and resources needed to perform log management functions.

Create and Maintain a Log Management Infrastructure

A log management infrastructure consists of the hardware, software, networks, and media used to generate, transmit, store, analyze, and dispose of log data. Log management infrastructures typically perform several functions that support the analysis and security of log data.

Provide Support for Staff with Log Management Responsibilities

To ensure that log management for individual systems is performed effectively throughout the organization, the administrators of those systems should receive adequate support.

Establish a Log Management Operational Process

The major log management operational processes typically include configuring log sources, performing log

analysis, initiating responses to identified events, and managing long-term storage.

What Events Should Be Logged for SANs?

For storage networks the same type of data should be collected as for other network devices, with focus on the storage management systems and any infrastructure that supports the SAN, such as the switches and servers. According to the SANS Institute, the top five most essential log reports[19] are as follows.

Attempts to Gain Access Through Existing Accounts Failed authentication attempts can be an indication of a malicious user or process attempting to gain network access by performing password guessing. It can also be an indication that a local user account is attempting to gain a higher level of permissions to a system.

Failed File or Resource Access Attempts Failed file or resource access attempts is a broad category that can impact many different job descriptions. In short, failed access attempts are an indication that someone is attempting to gain access to either a nonexistent resource or a resource to which they have not been granted the correct permissions.

Unauthorized Changes to Users, Groups and Services The modification of user and group accounts, as well as system services, can be an indication that a system has become compromised. Clearly, modifications to all three will occur legitimately in an evolving network, but they warrant special attention because they can be a final indication that all other defenses have been breached and an intrusion has occurred.

Systems Most Vulnerable to Attack As indicated in the original SANS Top 10 Critical Vulnerabilities list as well as the current Top 20, one of the most important steps you can take in securing your network is to stay up to date on patches. In an ideal world all systems would remain completely up to date on the latest patches; time management, legacy software, availability of resources, and so on can result in a less than ideal posture. A report that identifies the level of compliance of each network resource can be extremely helpful in setting priorities.

Suspicious or Unauthorized Network Traffic Patterns Suspect traffic patterns can be described as unusual or unexpected traffic patterns on the local network. This not only includes traffic entering the local network but traffic leaving the network as well. This report option requires a certain level of familiarity with what is "normal" for the local network. With this in mind, administrators need to be knowledgeable of local traffic patterns to make the best use of these reports. With that said, there are some typical traffic patterns that can be considered to be highly suspect in nearly all environments.

19. SANS Institute, www.sans.org/free_resources.php.

6. SUMMARY

The financial and IT resource benefits of consolidating information into a storage area network are compelling, and our dependence on this technology will continue to grow as our data storage needs grow exponentially. With this concentration and consolidation of critical information come security challenges and risks that must be recognized and appropriately addressed. In this chapter we covered these risks as well as the controls and processes that should be employed to protect the information stored on a SAN. Finally, we have emphasized why encryption of data at rest and in flight is a critical protection method that must be employed by the professional SAN administrator. Our intention is for you to understand all these risks to your SAN and to use the methods and controls described here to prevent you or your company from becoming a data loss statistic.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The Storage Network Industry Association (SNIA)[2] defines a SAN as a data storage system consisting of various storage elements, storage devices, computer systems, and/or appliances, plus some of the control software, all communicating in efficient harmony over a network.
2. True or False? Perhaps a main reason SANs have emerged as the leading storage option is because they can often alleviate many if not all the data storage "pain points" of IT managers.
3. True or False? SAN security is important because there is more concentrated, centralized, high-value data at risk than in normal distributed servers with built-in, smaller-scale storage solutions.
4. True or False? Some large-scale security gains have occurred by intercepting information incrementally over time, but the vast majority of breaches involve access or loss of data from the corporate SAN.

5. True or False? In its advanced form, a SAN is a number of servers attached to a storage array using a switch.

Multiple Choice

1. Specialized switches called ___________ are at the heart of a typical SAN. Switches provide capabilities to match the number of host SAN connections to the number of connections provided by the storage array.
   A. SAN switches
   B. Location technology
   C. Promotional email
   D. Malformed request DoS
   E. Data controller
2. What is file-level data storage providing data access to many different network clients?
   A. Network attached storage (NAS)
   B. Location technology
   C. Valid
   D. Load-Based DoS
   E. Bait
3. When one or more SAN switches are connected, a _____is created.
   A. Data minimization
   B. Fabric
   C. Target access
   D. Strong narrative
   E. Security
4. Host servers and storage systems are connected to the SAN fabric through ______ in the fabric.
   A. Call data floods
   B. Greedy strategy
   C. Ports
   D. SAN protocol
   E. Taps
5. What is a storage device that is designed to hold, manage, label, and store data to tape?
   A. Irrelevant
   B. Tape library
   C. IP storage access
   D. Configuration file
   E. Server policy

Risk Management

Sokratis K. Katsikas
University of Piraeus

Integrating security measures with the operational framework of an organization is neither a trivial nor an easy task. This explains to a large extent the low degree of security that information systems operating in contemporary businesses and organizations enjoy. Some of the most important difficulties that security professionals face when confronted with the task of introducing security measures in businesses and organizations are:

- The difficulty to justify the cost of the security measures
- The difficulty to establish communication between technical and administrative personnel
- The difficulty to assure active participation of users in the effort to secure the information system and to commit higher management to continuously supporting the effort
- The widely accepted erroneous perception of information systems security as a purely technical issue
- The difficulty to develop an integrated, efficient and effective information systems security plan
- The identification and assessment of the organizational impact that the implementation of a security plan entails

The difficulty in justifying the cost of the security measures, particularly those of a procedural and administrative nature, stems from the very nature of security itself. Indeed, the justification of the need for a security measure can only be proved "after the (unfortunate) event", whereas, at the same time, there is no way to prove that already implemented measures can adequately cope with a potential new threat. This cost does not only pertain to acquiring and installing mechanisms and tools for protection. It also includes the cost of human resources, the cost of educating and making users aware, and the cost for carrying out tasks and procedures relevant to security.
